Figure 57.1-20 (Figure Not Available) Femoral vein (A) anatomy and (B) cannulation technique. (From American Heart Association: *Textbook of Pediatric Advanced Life Support*. Dallas, American Heart Association, 1994, with permission. © 1994, American Heart Association.)

first dose is ineffective, it may be repeated every 3?min or increased to 0.1–0.2?mg/kg dose. Vasopressin may also be effective as a one-time dose (40?U in adults) after epinephrine; this is not recommended for children younger than 8 yr of age. Atropine may be effective for pulseless electrical activity, bradycardia, or asystole. Amiodarone is indicated in patients with ventricular fibrillation or pulseless ventricular tachycardia that is shock refractory; lidocaine and procainamide are second-choice alternate drugs. *Torsades de pointes* may respond to intravenous administration of 25?mg/kg of magnesium sulfate.

Intravenous or intraosseous fluids should be normal saline or lactated Ringer without glucose to support the circulation and to avoid hyperglycemia, which is a poor prognostic factor during an arrest.

Arterial Access.

Arterial catheters require special care for insertion and subsequent management because the blood flow to tissue can be compromised and considerable hemorrhage can occur if a catheter is dislodged. In most instances, the child should be in the pediatric intensive care unit (PICU). The adequacy of perfusion distal to the catheter must be monitored (e.g., warmth, capillary filling, edema). Catheters usually need to be heparinized (0.5–1?U/mL) to minimize clotting. The *radial artery* lies on the lateral side of the anterior wrist, just medial to the styloid process of the radius. When cannulating this vessel at or beyond the crease of the wrist, the superficial branch of the radial artery is being punctured. The *ulnar artery* is used much less often than the radial. At 2–3?cm above the wrist it becomes superficial, lying just lateral to the tendon of flexor carpi ulnaris. Although it is larger than the radial artery, the proximity of the ulnar artery to the ulnar nerve can pose additional risk.

An ulnar or radial artery occasionally may be absent or very small, and cannulation of the normal-sized radial or ulnar vessel may compromise blood flow to the hand. The **Allen test** is used to identify this possibility and consists of simultaneous compression of both the radial and ulnar arteries, instructing patients to clench the fist several times (to blanch the palm of the hand by propelling venous blood upward into the forearm), followed by release of pressure over one of the vessels and observation of how fast and how well the hand regains normal color. The test is then repeated with release of pressure over the other vessel. If, in both cases, the hand quickly becomes pink, it can be adequately perfused with only one of the two main arteries intact, and even if the cannulated artery were to become blocked (a very rare event), the hand would still be adequately perfused.

The *brachial artery* is easily palpable between the brachialis and biceps muscles, on the medial side of the arm, just above the elbow. The median nerve is just medial and may even lie superficial to the artery. Because cannulating this artery may compromise blood flow distally in the limb, only small catheters should be used (i.e., 22 gauge or smaller) and placed distal to the takeoff of the deep brachial artery. Anatomic landmarks and technique for cannulating or sampling from the *femoral artery* are identical to those for the femoral vein (see Fig. 57–20 (Figure Not Available)). The *dorsalis pedis artery* lies on the dorsum of the foot between the tendons of the tibialis anterior and flexor hallucis longus and is usually palpable. However, cannulation requires immobilization of the foot to minimize the risk of

dislodging the catheter with flexion and extension of the ankle. Alternatively, cannulation of the *posterior tibial artery* as it passes posterior to the medial malleolus involves risk to the underlying tibial nerve if profuse bleeding occurs.

Intraosseous Line Placement.

Intraosseous needles are special rigid large-bore needles that resemble Jamshidi needles for marrow aspiration. There are special flanges on the side of the needle hub and a stylet, which prevents the wedging of bone fragments inside the needle lumen as it passes into the marrow. The most common sites for insertion are the upper tibia (with care taken to avoid traversing the epiphyseal plate), the sternum, and the anterior superior iliac spine. Once positioned in the marrow space, the needle can be used to deliver nearly all intravenous fluids and blood products. Because such needles are often inserted in haste, consideration should be given to empirical antibiotic coverage after the needle is placed and the patient stabilized.

Thoracentesis and Chest Tube Placement (see Chapter 404).

Thoracentesis is the placement of a needle or catheter (chest tube) into the pleural space to evacuate fluid, blood, or air. Most insertions are performed in an intercostal space between the 4th and 9th ribs, along the midclavicular line in the anterior chest wall (in adolescents and adults), or in the plane of the midaxillary line. After a skin incision is made, dissection through the chest wall is accomplished in layers, using blunt dissection techniques. The needle (and later chest tube) that enters the pleural space should penetrate the intercostal space by passing over the superior edge of the lower rib, because there are larger vessels along the inferior edge of the rib. The chest tube should lie anterior in the pleural space for air and posterior for fluid accumulation. Final penetration of the intercostal membranes, to enter the pleural space, often takes considerable force, and the instrument (usually a hemostat) inserted into the pleural cavity should be grasped in such a way that there is no risk of uncontrolled deep penetration into the mediastinum, with possible contusion of the lung or heart. After the chest tube is inserted, it

TABLE 57.1-6 -- Potentially Treatable Conditions Associated with Cardiac Arrest

Condition	Common Clinical Settings	Corrective Actions
Acidosis	Pre-existing acidosis, diabetes, diarrhea, drugs and toxins, prolonged resuscitation, renal disease, and shock	Reassess adequacy of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement Hyperventilate Consider intravenous bicarbonate if pH <7.20 after above actions have been taken
Cardiac tamponade	Hemorrhagic diathesis, cancer, pericarditis, trauma, after cardiac surgery, and after myocardial infarction	Administer fluids; obtain bedside echocardiogram, if available Perform pericardiocentesis. Immediate surgical intervention is appropriate if pericardiocentesis is unhelpful but cardiac tamponade is known or highly suspected
Hypothermia	Alcohol abuse, burns, central nervous system disease, debilitated patient, drowning, drugs and toxins, endocrine disease, history of exposure, homelessness, extensive skin disease, spinal cord disease, and trauma	If hypothermia is severe (temperature < 30℃), limit initial shocks for ventricular fibrillation or pulseless ventricular tachycardia to three; initiate active internal rewarming and cardiopulmonary support. Hold further resuscitation medications or shocks until core temperature is > 30℃ If hypothermia is moderate (temperature 30–34℃), proceed with resuscitation (space medications at intervals greater than usual), passively rewarm, and actively rewarm truncal body areas
Hypovolemia, hemorrhage, anemia	Major burns, diabetes, gastrointestinal losses, hemorrhage, hemorrhagic diathesis, cancer, pregnancy, shock, and trauma	Administer fluids Transfuse packed red cells if hemorrhage or profound anemia is present Thoracotomy is appropriate when a patient has cardiac arrest from penetrating trauma and a cardiac rhythm and the duration of cardiopulmonary resuscitation before thoracotomy is <10?min
Hypoxia	Consider in all patients with cardiac arrest	Reassess technical quality of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement

Hypomagnesemia	Alcohol abuse, burns, diabetic ketoacidosis, severe diarrhea, diuretics, and drugs (e.g., cisplatin, cyclosporine, pentamidine)	Administer 1–2?g magnesium sulfate intravenously over 2?min
Myocardial infarction	Consider in all patients with cardiac arrest, especially those with a history of coronary artery disease or pre-arrest acute coronary syndrome	Consider definitive care (e.g., thrombolytic therapy, cardiac catheterization or coronary artery reperfusion, circulatory-assist device, emergency cardiopulmonary bypass)
Poisoning	Alcohol abuse, bizarre or puzzling behavioral or metabolic presentation, classic toxicologic syndrome, occupational or industrial exposure, and psychiatric disease	Consult toxicologist for emergency advice on resuscitation and definitive care, including appropriate antidote Prolonged resuscitation efforts may be appropriate; immediate cardiopulmonary bypass should be considered, if available
Hyperkalemia	Metabolic acidosis, excessive administration of potassium, drugs and toxins, vigorous exercise, hemolysis, renal disease, rhabdomyolysis, tumor lysis syndrome, and clinically significant tissue injury	If hyperkalemia is identified or strongly suspected, treat with all of the following: 10% calcium chloride (5–10?mL by slow intravenous push; do not use if hyperkalemia is secondary to digitalis poisoning), glucose and insulin (50?mL of 50% dextrose in water and 10 units of regular insulin intravenously), sodium bicarbonate (50?mmol intravenously; most effective if concomitant metabolic acidosis is present), and albuterol (15–20?mg nebulized or 0.5?mg by intravenous infusion)
Hypokalemia	Alcohol abuse, diabetes, use of diuretics, drugs and toxins, profound gastrointestinal losses, hypomagnesemia	If profound hypokalemia (<2–2.5?mmol of potassium per liter) is accompanied by cardiac arrest, initiate urgent intravenous replacement (2?mmol/min intravenously for 10–15?mmol); then reassess
Pulmonary embolism	Hospitalized patient, recent surgical procedure, peripartum, known risk factors for venous thromboembolism, history of venous thromboembolism, or prearrest presentation consistent with diagnosis of acute pulmonary embolism	Administer fluids; augment with vasopressors as necessary Confirm diagnosis, if possible; consider immediate cardiopulmonary bypass to maintain patient's viability Consider definitive care (e.g., thrombolytic therapy, embolectomy by interventional radiology or surgery)
Tension pneumothorax	Placement of central catheter, mechanical ventilation, pulmonary disease (including asthma, chronic obstructive pulmonary disease, and necrotizing pneumonia), thoracentesis, and trauma	Needle decompression, followed by chest tube insertion

From Eisenberg MS, Mengert TJ: Cardiac resuscitation. N Engl J Med 2001; 344:1304–13.

TABLE 57.1-7 -- Medications for Cardiac Arrest and Symptomatic Arrhythmias

Drug	Dosage (Pediatric)	Remarks
Adenosine	0.1?mg/kg	Rapid IV/IO bolus
	Repeat dose: 0.2?mg/kg	Rapid flush to central circulation
	Maximum single dose: 12?mg	Monitor ECG during dose.
Amiodarone for pulseless VF/VT	5?mg/kg IV/IO	Rapid IV bolus
Amiodarone for perfusing tachycardias	Loading dose: 5?mg/kg IV/IO	IV over 20–60?min
	Maximum dose: 15?mg/kg/day	Routine use in combination with drugs prolonging QT interval is *not* recommended. Hypotension is most frequent side effect.
Atropine sulfate*	0.02?mg/kg	May give IV, IO, or ET.

	Minimum dose: 0.1?mg	Tachycardia and pupil dilation may occur but *not* fixed dilated pupils.
	Maximum single dose: 0.5?mg in child, 1.0?mg in adolescent. May repeat once.	
Calcium chloride 10% = 100?mg/mL (= 27.2?mg/mL elemental Ca)	20?mg/kg (0.2?mL/kg) IV/IO	Give slow IV push for hypocalcemia, hypermagnesemia, calcium channel blocker toxicity, preferably via central vein. Monitor heart rate; bradycardia may occur.
Calcium gluconate 10% = 100?mg/mL (= 9?mg/mL elemental Ca)	60–100?mg/kg (0.6–1.0?mL/kg) IV/IO	Give slow IV push for hypocalcemia, hypermagnesemia, calcium channel blocker toxicity, preferably via central vein.
Epinephrine for symptomatic bradycardia[*]	IV/IO: 0.01?mg/kg (1:10,000, 0.1?mL/kg) ET: 0.1?mg/kg (1:1,000, 0.1?mL/kg)	Tachyarrhythmias, hypertension may occur.
Epinephrine for pulseless arrest[*]	First dose: IV/IO: 0.01?mg/kg (1:10,000, 0.1?mL/kg) ET: 0.1?mg/kg (1:1,000, 0.1?mL/kg) Subsequent doses: Repeat initial dose or may increase up to 10 times (0.1?mg/kg, 1:1,000, 0.1?mL/kg) Administer epinephrine every 3–5?min IV/IO/ET doses as high as 0.2?mg/kg of 1:1,000 may be effective.	
Glucose (10% or 25% or 50%)	IV/IO: 0.5–1.0?g/kg • 1–2?mL/kg 50% • 2–4?mL/kg 25% • 5–10?mL/kg 10%	For suspected hypoglycemia; avoid hyperglycemia.
Lidocaine[*]	IV/IO/ET: 1?mg/kg	Rapid bolus
Lidocaine infusion (start after a bolus)	IV/IO: 20–50?µg/kg/min	1 to 2.5?mL/kg/h of 120?mg/dL solution or use “rule of 6”
Magnesium sulfate (500?mg/mL)	IV/IO: 25–50?mg/kg, Maximum dose: 2?g per dose	Rapid IV infusion for torsades or suspected hypomagnesemia; 10- to 20-minute infusion for asthma that responds poorly to ß-adrenergic agonists.
Naloxone[*]	(=5 years or (=20?kg: 0.1?mg/kg >5 years or > 20?kg: 2.0?mg	For total reversal of narcotic effect. Use small repeated doses (0.01–0.03?mg/kg) titrated to desired effect.
Procainamide for perfusing tachycardias (100?mg/mL and 500?mg/mL)	Loading dose: 15?mg/kg IV/IO	Infusion over 30–60?min; routine use in combination with drugs prolonging QT interval is *not* recommended.
Sodium bicarbonate (1?mEq/mL and 0.5?mEq/mL)	IV/IO: 1?mEq/kg per dose	Infuse slowly and only if ventilation is adequate.

IV = intravenous; IO = intraosseous; ET = endotracheal; ECG = electrocardiogram; VF = ventricular fibrillation; VT = ventricular tachycardia.

From Emergency Cardiac Care Committee Guidelines on Pediatric Advanced Life Support. Circulation 2000;102: I291–I342.

* *For endotracheal administration use higher doses (2–10 times the IV dose); dilute medication with normal saline to a volume of 3–5?mL and ollow with several positive-pressure ventilations.*

should be secured firmly to the chest wall and connected to a source of suction (e.g., Pleurovac) at a pressure of 15–20?cm H_2O. A radiograph should be obtained to verify chest tube placement and evacuation of the pleural space.

Pericardiocentesis.

When fluid, blood, or gas accumulates in the pericardial sac, a danger is that the heart will be compressed and will not be able to fill and empty with normal volumes of blood, leading to diminution in cardiac output. The cardinal signs of such a restrictive pericardial effusion are tachycardia, hypotension, and decreasing oxygen saturation. Pericardiocentesis is needle aspiration of the sac performed with or without ultrasound verification of needle placement or attachment of a recording electrode. After proper patient positioning, sterile cleansing of the area around the xiphoid process, and sedation/analgesia, pericardiocentesis begins with a short incision in the skin just below the xiphoid process. The needle should be a 22- or 20-gauge spinal needle, 6.25?cm (2.5 inches) in length. The proximal end of the needle is attached to a stopcock and collection syringe. The needle is inserted through the incision and then positioned so that it points toward the space between the left nipple and the medial end of the clavicle. Once the needle is through the skin, its angle should be flattened considerably with respect to the chest wall so that penetration is not too deep (in larger children or adults, the angle must be steeper). During insertion, the syringe attached to the needle is continuously aspirated with

gentle pressure so that when the needle enters the pericardial space there will be a rush of gas or fluid. Once the procedure is concluded, a sterile dressing should be placed over the skin incision and a chest radiograph obtained to rule out any complications.

Equipment and Drugs for Resuscitation.

An emergency department or intensive care unit should have a full supply of resuscitation equipment that is frequently checked for both presence and functionality (e.g., available catheters and tubes in appropriate sizes and charged batteries). The supplies needed for a pediatric office or clinic emergency are presented in Chapter 51 . Those required for a PICU or emergency department are presented in Box 57–3 . See Table 57–7 for drugs that may be urgently required for resuscitation. Some resuscitations involve difficulty in establishing vascular access, and a patient whose condition is rapidly deteriorating may die without such access if medications are not administered. In such cases, if an airway has been established, certain drugs may be administered via the endotracheal tube.

Box 57.1-3. Supplies Needed for Pediatric Intensive Care/Emergency Department

- Storage cart for equipment/materials
- Defibrillator/portable ECG monitor
- Oxygen cylinder
- Airway equipment:
  - Laryngoscope handle with batteries
  - Assortment of blades–Miller 0, 1, 2, 3 and MacIntosh 2, 3
  - Large assortment of endotracheal tubes, cuffed and uncuffed, with stylets
  - Nasal and oral airways
  - Self-inflating resuscitation bags
  - Anesthesia bags with oxygen adapter

  - Nasal and oral airways
  - Self-inflating resuscitation bags
  - Anesthesia bags with oxygen adapter

- Suction equipment, including tongue blades, Yankauer suction tip, several catheters
- Various nasogastric tubes
- Tapes, sponges, IV adapters, T connectors, stopcocks
- Masks for bag-mask ventilation, many sizes
- Mapleson system with varied bag sizes
- Cardiac equipment:
  - Cardiac arrest board for compressions
  - IVs, butterflies, intraosseous needles
  - Blood pressure measuring equipment
  - Several unit doses of epinephrine, bicarbonate, calcium chloride, lidocaine, naloxone D_{25} W
- IV fluids and medications:
  - Various crystalloid and colloid fluids
  - Fully equipped IV tray–catheters, alcohol, needles, tape, tourniquets, armboards
  - Cutdown tray
  - Umbilical catheter tray
  - Tracheostomy tray
  - Chest tube tray
  - Pleurovac pump
  - Cardiac surgery open chest tray (if unit cares for postoperative hearts)

Pleurovac pump

Cardiac surgery open chest tray (if unit cares for postoperative hearts)

ICP monitor tray

General minor surgical procedure tray

Military antishock trousers (MAST) kit

Warm packs, sandbags, and so on

Monitoring equipment: pulse oximetry, ECG, end-tidal CO_2 , blood pressure

ECG = electrocardiogram; IV = intravenous; ICP = intracranial pressure.

POSTRESUSCITATION CARE

When resuscitation is successful, continuous PICU care is usually needed to attend to the potential postischemic multiple organ dysfunction syndrome and continued need for cardiac inotropic support. Most patients do not require hyperventilation. Hyperglycemia and hyperthermia should be avoided. Continuous observation for immediate neurologic deterioration and long-term permanent neurodevelopment sequelae is imperative.

When resuscitation fails and the patient dies, attention is naturally focused on comforting the grieving family. Members of the medical team also need time to adjust to the events and understand how and why their efforts did not succeed. The more senior members of a team should recognize and acknowledge the contributions of those involved in the resuscitation and should convey to the family a detailed description of what took place. Increasingly, families may be present at resuscitations and may need a special kind of “debriefing” to help them accept what they have just witnessed. Where appropriate, families should be reassured that any further data that become available in the days and weeks after a death (autopsy results, etc.) can be shared with them if that should be their wish. Finally, someone on the team must be mindful of the legal and procedural duties involved in a death, such as notification of the coroner and contact with the organ/tissue transplant bank, completion of the death certificate, and arrangements for disposition of the remains of the deceased, depending on local regulations, family wishes, and customs.

57.2 Shock

Lorry R. Frankel
Lawrence H. Mathers

Shock is an acute dramatic syndrome, characterized by inadequate circulatory provision of oxygen, so that the metabolic demands of vital organs and tissues are not met. Insufficient oxygen is delivered to support aerobic cellular metabolism. There is a shift to less efficient anaerobic metabolism, which leads to lactic acidosis (see Chapter 45.8). If inadequate tissue perfusion continues, various endocrine, vascular, inflammatory, metabolic, cellular, and systemic responses occur and the patient becomes more physiologically unstable (see Chapter 163). Shock is a progressive process, owing to the continued presence of the initiating factor plus exaggerated and potentially harmful neurohumoral, inflammatory, and cellular compensatory responses. Initially, shock may be compensated but then may progress to an uncompensated condition, which may still respond to therapy. Untreated shock will lead to irreversible tissue injury (irreversible shock) and death. The specific pattern of response and related pathophysiology, clinical manifestations, and treatments varies with the etiology of shock (Table 57–8). Hypovolemic (hemorrhage, diarrhea-dehydration) and septic shock are the most common causes of shock in children. Cardiogenic shock may be seen in neonates with congenital heart disease and in older patients immediately after repair of congenital heart defects.

Shock often leads to the systemic inflammatory response syndrome and the multiple organ dysfunction syndrome. Sepsis may be present without bacteremia, and bacteremia may be present without sepsis. Sepsis syndrome has more signs of poor tissue perfusion (decreased urine output, restlessness, lactic acidosis, hypoxia), whereas septic shock demonstrates hypotension with blood pressures falling less than the 5th percentile for age. Refractory septic shock is present if despite 1?hr of appropriate therapy shock persists.

TABLE 57.2-8 -- Clinical Classification of Shock

Type of Shock	Septic	Cardiogenic	Distributive	Hypovolemic	Obstructive
Characteristics					
	Infectious organisms release toxins that affect fluid distribution, cardiac output, and so on	Primary pump failure produces inadequate tissue perfusion; resultant metabolic acidosis further impairs cardiac function	Neurologic disturbances may cause uneven distribution of fluids, leading to acidosis Overdose of drugs can alter fluid distribution	Reduced fluid volume reduces cardiac output; metabolic acidosis can result from low intravascular volume and poor tissue perfusion; serious electrolyte abnormalities may occur	Poor cardiac output, cyanosis, hypotension, narrow pulse pressure
Sample Causes					
	Bacterial	Ischemic insult	Neurogenic (disturbance of vasomotor tone)	Enteritis	Tension pneumothorax, pericardial tamponade
	Viral	Cardiomyopathy		Hemorrhage	
	Fungal (all are more likely in immunocompromised)	Congenital heart disease	Anaphylaxis	Extensive burns	
			Toxins	Diabetes insipidus	
			Allergic reactions	Adrenal insufficiency	

Epidemiology.

Shock occurs in approximately 2% of all hospitalized children and adults in the United States (~400,000 cases/yr). The mortality rate is 20–50%. Most patients do not die in the acute hypotensive phase of shock but rather as a result of one or more complications associated with the shock state. Multiple organ dysfunction syndrome increases the probability of death (one organ system involved, 25%; two organ systems, 60%; three or more organ systems > 85%). The mortality of shock in infected patients increases as one progresses from sepsis to septic shock to refractory sepsis. The mortality rate of shock in pediatric patients has declined as a consequence of educational efforts (pediatric advanced life support [PALS]), which emphasize early recognition and intervention and rapid transfer of critically ill patients to a PICU via a transport service.

Pathophysiology.

Shock may result in multiple tissue injury through a number of pathways, which may vary depending on the stage of its development. Production or release of the inflammatory mediators is triggered by the infectious, ischemic, or hypoxic insult, which produces inadequate tissue perfusion. An additional spectrum of injury may occur during the reperfusion stage of shock when blood flow and oxygen delivery are restored to the previously injured tissues. Some of the inflammatory-mediator responses that occur during shock, especially due to infections, are referred to as the systemic inflammatory response syndrome (SIRS). Various inflammatory mediators such as tumor necrosis factor, platelet-activating factor, and proinflammatory interleukins are significant contributing agents to the development of SIRS. SIRS results in capillary fluid loss with edema formation and an unequal distribution of cardiac output further compromising oxygen delivery to the peripheral tissues (Chapter 163).

In the early phases of shock, a number of compensatory physiologic mechanisms act to maintain blood pressure (BP) and preserve tissue perfusion. These responses include increases of heart rate, stroke volume, and vascular smooth muscle tone, regulated through neurohormonal changes in sympathetic nervous system activation and other hormonal responses, to help preserve blood flow to vital organs such as the brain, heart, and kidneys. The respiratory rate is increased to promote the excretion of CO_2 to compensate for increased CO_2 production and the metabolic acidosis. Increased renal excretion of hydrogen ions and retention of bicarbonate occurs in an effort to maintain normal pH (see Chapter 45.8). Maintenance of vascular volume is facilitated by the renin-angiotensin and the atrial natriuretic factor axes (through regulation of sodium), steroid hormone and catecholamine synthesis and release, and secretion of antidiuretic hormone. Despite these compensatory mechanisms, intravascular fluid leaks into the interstitial extracellular space owing to vascular endothelial cell injury.

When the compensatory mechanisms cannot maintain adequate tissue perfusion, further tissue injury, and cell (and eventually patient) death occur (Box 57–4). It is common for more than one of these processes to occur simultaneously. Fluid loss commonly accompanies vomiting and diarrhea, hemorrhagic trauma, and severe burns and can result in an initial increase in vascular resistance as the body attempts to maintain BP and restore circulating intravascular volume. Subsequently, hypotension will develop and produce tissue ischemia. Significant electrolyte alterations may also accompany the fluid loss. When there is a pre-existing *low plasma oncotic pressure*, as occurs with the nephrotic syndrome, malnutrition or hepatic dysfunction, or acute severe burns, there may be excessive capillary leaking; this may result in large fluid loss, which exacerbates shock, produces edema, and potentially worsens the respiratory status. *Abnormal vasodilation* results in vasodilatory shock and is usually caused by sepsis, hypoxia, poisonings (carbon monoxide, cyanide, metformin), anaphylaxis, neurogenic events, and mitochondrial dysfunction (Fig. 57–21). The lower systemic vascular resistance (SVR) is usually accompanied by an increase in cardiac

Box 57.2-4. Pathophysiology of Shock

EXTRACORPOREAL FLUID LOSS

Hypovolemic shock–may be due to the direct blood loss through hemorrhage or abnormal loss of body fluids (diarrhea, vomiting, burns, diabetes insipidus, nephrosis)

LOWERING PLASMA ONCOTIC FORCES

Hypovolemic shock may also result from hypoproteinemia (liver injury, or as a progressive complication of increased capillary permeability).

ABNORMAL VASODILATION

Distributive shock (neurogenic, anaphylaxis, or septic shock) occurs when intravascular fluid shifts into the extracellular space owing to increase in the rate of blood flow, and blood volume, or hydrostatic pressure in the vascular compartment (sympathetic blockade, local substances affecting permeability, acidosis, drug effects, spinal cord transection, other).

INCREASED VASCULAR PERMEABILITY

Sepsis may change the capillary permeability in the absence of any change in capillary hydrostatic pressure (endotoxins from sepsis, excess histamine release in anaphylaxis, and so on).

pressure (endotoxins from sepsis, excess histamine release in anaphylaxis, and so on).

CARDIAC DYSFUNCTION

Peripheral hypoperfusion may result from any condition that affects the heart's ability to pump blood efficiently (ischemia, acidosis, drugs, constrictive pericarditis, pancreatitis, sepsis, other).

Figure 57.2-21 Mechanisms of vasodilatory shock. Septic shock and states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate ATP-sensitive and calcium-regulated potassium channel (K_{ATP} and K_{CA}, respectively) in vascular smooth muscle, and lead to depletion of vasopressin. The abbreviation cGMP denotes cyclic guanosine monophosphate. (From Landry DW, Oliver JA: The pathogenesis of vasodilatory shock. *N Engl J Med* 2001;345: 588–95.)

output and a redistribution of blood flow, hence the term *distributive shock*. In addition, prolonged states of intense vasoconstriction due to hemorrhagic or cardiogenic shock may lead to terminal vasodilatory shock. *Increased vascular permeability* is most common with sepsis or anaphylaxis but is also seen in hemorrhagic shock. Bacterial products (endotoxin) and inflammatory mediators (TNF) are implicated and result in significant depletion of intravascular volume. *Cardiogenic shock*, although rare in children, may be associated with a cardiomyopathy, severe congenital heart disease, significant dysrhythmias, or immediately after surgery for congenital heart disease (see Chapter 427). Sepsis, pancreatitis, and SIRS can produce direct myocardial depressant effects, adding a cardiogenic component to patients with septic shock.

A significant misconception is that shock occurs only with low BP (hypotension). Through various compensatory mechanisms, hypotension is often a late finding in shock. It represents an advanced state of *decompensated shock* and has a high mortality rate. Conversely, if blood pressure is low but tissue perfusion is adequate to meet the metabolic demands of the body, shock may not be present. Shock may be present with normal BP if other factors do not permit the patient to maintain adequate tissue oxygen delivery. Anemia and hypoxia will result in reduced oxygen delivery at any given cardiac output. Fever and trauma may increase tissue oxygen requirements. When any of the mechanisms leading to shock progress to the development of hypoxia and lactic acidosis, they pose an immediate risk to cardiac function, lessening the strength of contractions and predisposing to dysrhythmias. Persistent tissue ischemia (hypoxic decreased blood flow) in uncompensated shock results in a cascade of events that, if left uncorrected, result in irreversible shock and death.

The systemic response to an initiating event (infection) may be mediated by genetic polymorphisms of inflammatory genes (e.g., TNF) or its receptor. Patients with a genetic predisposition that causes a more profound inflammatory response are at the greatest risk for shock. Nitric oxide, one central regulator of the control of vascular smooth muscle tone, may soon be joined by locally produced carbon monoxide, for which evidence mounts that it may be a cell-signaling molecule, quite apart from its well-acknowledged role as a toxin. Heat-shock proteins lessen the effects of toxic oxidative molecules during septic shock and other insults to tissues and organs. Their regulation may enhance or modify the circulatory response to shock. Endotoxins involved in sepsis induce production of various inflammatory molecules such as the interleukins; adverse outcomes are associated with high-level inflammatory cytokines. Circulating anti-inflammatory cytokines may modify this response.

Septicemia and septic shock are discussed in Chapters 98 and 163 . The associated immune-mediated responses, particularly to endotoxin, leads to the development of SIRS. The vascular endothelium is one of the principal targets of these inflammatory reactions, and changes in the level of nitric oxide and other mediators are a final pathway for both host defense responses and regulation of blood flow to selected tissues (see Fig. 57–21). The production of and the response to these inflammatory mediators varies widely among individuals and may explain why some patients with sepsis who develop shock have a high-mortality and complications such as acute respiratory distress syndrome (ARDS) or hepatic failure.

Clinical Manifestations.

A classification of shock is presented in Table 57–8 . There is significant overlap in these categories, especially between septic and distributive shock. The clinical presentations of shock depend, in part, on the cause; however, if shock is unrecognized and untreated, a very similar untoward progression of clinical signs and pathophysiologic changes occurs and leads to a common final path (Table 57–9). The clinical features of shock also relate to the stage (duration vs. progression) of the process (early vs late).

Hypovolemic shock usually presents as changes in mental status, tachypnea, tachycardia, hypotension, cool extremities, and oliguria. Table 57–9 outlines the clinical signs of a progressive decrease in perfusion. Supine hypotension and tachycardia are hallmarks of hypovolemia. In adults, postural dizziness and tachycardia (pulse > 30 beats/min over supine value taken 1–2 minutes after standing while counting for 30 seconds) are helpful clues. Dry mucous membranes and a dry axilla and poor skin turgor are variably present. Hypovolemic shock may initially present as normal or only slightly cool distal extremities. *Septic shock* may present initially as compensated or “warm shock” with warm extremities (from peripheral vasodilation secondary to low SVR), bounding pulses and tachycardia (from high stroke volume and widened pulse pressure), tachypnea, adequate urination, and mild metabolic acidosis. In contrast, *cardiogenic shock* presents as cool extremities, delayed (> 2–3 seconds) capillary filling time, hypotension, tachypnea, increasing obtundation, and decreased urination (all caused by peripheral vasoconstriction and decreased cardiac output [see Chapter 427]). Uncompensated or “cool shock” (high vascular resistance, decreased cardiac output, oliguria) occurs late in the progression of shock, regardless of its etiology. Hemodynamic findings in various shock states are noted in Table 57–10 .

The transition from warm shock to cool shock is not always easy to identify. At the

cellular level, the increase in lactic acid production and very low mixed venous oxygen saturations, indicating inadequate oxygen delivery, are hallmarks of uncompensated shock. Measurement of the oxygen saturation of central mixed venous blood [Mv_{O_2}] from the pulmonary artery, right ventricle, right atrium, and superior or inferior vena cavae

can determine if overall peripheral oxygen delivery (the true standard for such measurements is the pulmonary artery) is adequate. The Mv_{O_2} should be 20–25% less than the arterial oxygen saturation (normally, the Mv_{O_2} is 75–80%). This can guide caregivers in the use of fluid support and inotropic agents to improve cardiac output in the treatment of shock.

An unusual form of shock is the *hemorrhagic shock encephalopathy syndrome* (HSES). This syndrome initially looks similar to heat stoke. It is usually seen in children younger than 3 yr old and is characterized by encephalopathy, fever, shock, watery diarrhea, severe disseminated intravascular coagulation (DIC), and renal and hepatic dysfunction. In addition to the hemodynamic changes associated with poor perfusion and hypotension, patients with HSES may develop seizures and other severe neurologic findings as a result of cerebral edema. These children have an associated rapid onset of abnormal liver function studies and coagulation tests. These abnormalities persist for 3–4 days. Therapy is directed at fluid resuscitation, maintaining adequate cardiac output, supporting the renal and hepatic failure, and ameliorating acute neurologic abnormalities. Other complications may include myoglobinuria due to rhabdomyolysis. These children have a very high mortality rate, and survivors have a high incidence of neurologic problems.

Treatment

INITIAL MANAGEMENT.

In most patients with early shock, a fluid bolus of 20?mL/kg of normal saline or lactated Ringer solution should be given rapidly. If it is not possible to insert an intravenous catheter into a peripheral vein within 90?sec or within three attempts, an intraosseous needle should be inserted to administer fluids (see Chapters 51 and 57.1). After this infusion, the patient is reassessed to determine if more fluid is

required or other forms of therapy should be initiated (i.e., antibiotics, vasoactive agents, or other types of fluids). Children in severe hypovolemic shock may require and tolerate fluid boluses totaling 60–80?mL/kg within the first 1–2?hr of presentation. However, the risk of fluid overload must be continually reassessed. If the child's hypovolemia is from loss of blood or protein-rich fluid, replacement with fresh frozen plasma, albumin, whole blood, or packed red blood cells may be appropriate. The use of dextrans (hydroxyethyl starch) or gelatins may be indicated if there is a need to increase plasma oncotic pressure but blood component therapy cannot be administered or is ineffective. There is continuing debate about the relative risks and benefits of choosing crystalloid solutions (normal saline, lactated Ringer solution) versus colloid (e.g., albumin, hetastarch) for fluid resuscitation. The ideal solution is one that remains in the intravascular space (does not produce edema), has a long half-life, and is not toxic. To date, no solution fulfills these criteria. Some hydroxyethyl starches may produce an osmotic renal injury and predisposes the patient to acute renal failure.

If, after what is considered appropriate fluid resuscitation, the patient continues to demonstrate poor perfusion and shock, vasoactive agents are needed. The overall goal is to restore oxygen delivery to vital tissues. This can be accomplished by improving oxygen-carrying capacity (maintain normal hematocrit at 35–40%), improving oxygen saturation (95–99%) and Pa_{O_2} (if severely anemic), and enhancing a depressed cardiac output. The latter is influenced by the heart rate, preload (fluid status), afterload (systemic vascular resistance), and state of myocardial contractility. Oxygen delivery need not exceed (supranormal) normal expectations because the “supply-dependency” oxygen relationship is not believed to be a critical factor in managing shock. When achieved, supranormal oxygen delivery does not improve outcome and may increase complications. When oxygen requirements are excessively high (seizures, burns, fever), it may be easier to reduce the metabolic stress with direct therapy (anticonvulsants, antipyretic agents).

CARDIOVASCULAR MANAGEMENT

(also see Chapters 427 and 434). Septic, cardiogenic, distributive, and, rarely, hypovolemic shock may require various drugs to stimulate heart rate (*chronotropic*), cardiac contractility (*inotropic*), and enhance peripheral vascular resistance (*blood pressure*). These agents should be infused through a central venous catheter in an intensive care unit. These drugs increase oxygen consumption and the risk of dysrhythmias (Table 57–11). Dopamine is probably the most frequently used initial agent and is preferred for cardiogenic shock. Epinephrine has many of the same properties as dopamine; however, it is more effective in increasing peripheral vascular tone and has a greater effect on the heart. Epinephrine also

TABLE 57.2-11 -- **Cardiovascular Drug Treatment of Shock**

Drug	Effect(s)	Dose Range	Comments
Dopamine	Strengthens contractions (throughout dose range)	Low dose = 1–5?µg/kg/min	Increasing risk of dysrhythmias at high dose
	Increases renal blood flow (low/intermediate doses)	Intermediate dose = 5–15?µg/kg/min	Should be administered in central vein
	Vasoconstriction (high doses)	High dose = 15–25?µg/kg/min	
Epinephrine	Increases heart rate and strength of contractions	0.05–3.0?µg/kg/min	May lessen renal perfusion
	Potent vasoconstrictor		Causes high O_2 consumption in the heart
			High risk of dysrhythmias
Dobutamine	Increases strength of heart contraction	1–20?µg/kg/min	Has very weak vasoconstriction (high dose)
	Little effect on heart rate		Good for cardiogenic shock; strengthens heart contraction and produces afterload reduction
	Peripheral vasodilator, especially in vessels to viscera		
Isoproterenol	Strong effect on increasing heart rate	0.05–2.0?µg/kg/min	Increases O_2 consumption
	A potent bronchodilator		Potential for producing dysrhythmias
	Virtually no effect on strength of heart contraction		
Norepinephrine	Strong vasoconstrictor	0.05–1.5?µg/kg/min	Produces short-run rise in blood pressure (high SVR)
	Weak effect on strength of heart contraction		Causes increase in O_2 consumption, tendency for dysrhythmias

Phenylephrine	Strong vasoconstrictor	0.5–2.0?µg/kg/min	Can cause sudden hypertension
	Can be used to slow tachycardia through reflex cardiac slowing		Causes increase in O_2 consumption
Amrinone	Potent inotrope	Load with 1.5–5?mg/kg bolus over 20?min, followed by 5–10?µg/kg/min	Phosphodiesterase inhibitor—slows cyclic AMP breakdown
	Potent chronotrope		
	Peripheral vasodilator		

O_2 = oxygen; SVR = systemic vascular resistance; AMP = adenosine monophosphate.

causes a greater increase in myocardial oxygen consumption and poses a greater risk of dysrhythmias. Dobutamine has a more selective action than either of these agents in cardiogenic shock and provides afterload reduction. Isoproterenol may produce severe tachycardia and decrease coronary perfusion and produce myocardial ischemia. Norepinephrine and phenylephrine are particularly effective in counteracting low systemic vascular resistance. It is not unusual to combine various inotropic agents. Commonly used combinations include low-dose dopamine with epinephrine, dobutamine with norepinephrine, or dopamine with dobutamine. These agents are titrated by continuous intravenous infusions with careful monitoring of BP with an indwelling intra-arterial catheter.

Because of its central role in vasodilatory shock and the demonstration of vasopressin depletion, there is a rationale for using intravenous vasopressin to treat shock that is unresponsive to catecholamines. In addition, in some patients with septic shock and in all patients who are on or who were recently weaned from steroids, intravenous hydrocortisone in stress doses should be started. A significant number of patients with septic shock have secondary adrenal insufficiency; a spot serum cortisol level will confirm the diagnosis, but empirical therapy may need to be started before the laboratory result is known. Afterload reduction is seldom indicated in early shock but may be useful in the recovery phase of cardiogenic shock (Table 57–12). Amrinone and more often milrinone have demonstrated beneficial effects in the advanced treatment of cardiogenic

TABLE 57.2-12 -- **Vasodilators/Afterload Reducers**

Nitroprusside	Vasodilator (mainly arterial)	0.5–1.0?µg/kg/min	Rapid effect Prolonged use (>48?hr risks cyanide toxicity)
Nitroglycerin	Vasodilator (mainly venous)	1.0–20?µg/kg/min	Rapid effect Risk of high intracranial pressure
Prostaglandin E1	Vasodilator	0.05–0.2?µg/kg/min	Can lead to hypotension
	Maintains open ductus arteriosus in newborn		Risk of apnea when given continuously
Hydralazine	Direct arteriolar smooth muscle dilator	0.1–2.0?mg/kg; may start with low dose and repeat with higher doses to effect	Hypotension and reflex tachycardia Lupus-like effect in chronic use

shock because they increase contractility and promote afterload reduction. Intravenous methylene blue and angiotensin II have also been used in a few patients with unresponsive shock. Methylene blue increases myocardial performance and decreases inotropic drug use and maintains oxygen delivery. Angiotensin II is 40 times more potent as a vasoconstricting agent as norepinephrine.

OTHER MODES OF SUPPORT IN SHOCK.

Goal-directed therapy for complications in shock is noted in Table 57–13 . Coagulation disorders are frequently found in severe shock; DIC is discussed in Chapter 474 . Correction of acidosis and hypocalcemia is discussed in Chapters 48.8 and 48.9 , respectively.

Rarely, other invasive techniques may be needed to support children in shock who are not responding to fluid, pharmacologic support, or other modes of treatment when the cause of shock is considered treatable and reversible. Extracorporeal membrane oxygenation (ECMO) may be effective in treating young children with septic shock or severe cardiogenic shock, as a bridge to recovery or transplant in patients who have undergone cardiac surgery, and in those who have difficulty being weaned from bypass. Left ventricular or biventricular assist devices have also been used to manage severe cardiomyopathy and cardiogenic shock as a bridge to transplantation or until the disease process has reversed itself. Dialysis and hemofiltration have been used to manage fluid overload or pulmonary edema and remove inflammatory mediators.

TABLE 57.2-13 -- **Goal-Directed Therapy of Organ System Dysfunction in Shock**

System	Disorders	Goals	Therapies

Respiratory	ARDS Respiratory muscle fatigue Central apnea	Prevent/treat: hypoxia and respiratory acidosis Prevent barotrauma Decrease work of breathing	Oxygen Early endotracheal intubation and mechanical ventilation PEEP Permissive hypercapnia High-frequency ventilation ECMO
Renal	Prerenal failure Renal failure	Prevent/treat: hypovolemia, hypervolemia, hyperkalemia, metabolic acidosis, hyper/ hyponatremia, and hypertension	Judicious fluid resuscitation Monitor serum electrolytes Low-dose dopamine Furosemide (Lasix) Dialysis, ultrafiltration, hemofiltration
Hematologic	Coagulopathy (DIC)	Prevent/treat: bleeding	Vitamin K Fresh frozen plasma Platelets
	Thrombosis	Prevent/treat: abnormal clotting	Heparinization Activated protein C Antithrombin III
Gastrointestinal	Stress ulcers	Prevent/treat: gastric bleeding Avoid aspiration, abdominal distention	H_2 blocking agents or proton pump inhibitors
	Ileus Bacterial translocation	Avoid mucosal atrophy	Nasogastric tube Early enteral feedings
Endocrine	Adrenal insufficiency primary or secondary to chronic steroid therapy	Prevent/treat: adrenal crisis	Stress dose steroids if previously on steroids Physiologic dose for presumed primary insufficiency in sepsis
Metabolic	Metabolic acidosis	Correct etiology Normalize pH	Treat hypovolemia (fluids), poor cardiac function (fluids, inotropic agents) Improve renal acid excretion Low-dose 0.5–2?mEq/kg of sodium bicarbonate if not responding and pH < 7.1 and ventilation (CO_2 elimination) is adequate

ARDS = acute respiratory distress syndrome; PEEP = positive end-expiratory pressure; DIC = disseminated intravascular coagulation; H_2 = histamine2 receptor; ECMO = extracorporeal membrane oxygenation.

Biologic mediators have shown promise in improving the outcome of septic shock; these include activated protein C and bactericidal permeability increasing protein.

57.3 Respiratory Distress and Failure

Lorry R. Frankel

Respiratory distress/failure is the primary diagnosis in close to 50% of children admitted to PICUs and is a common cause of cardiopulmonary arrests in children. There is a substantial variability by season, etiology, and severity of illness. Respiratory failure arises from derangements in pulmonary gas exchange. The four principal derangements are hypoventilation, diffusion impairment, intrapulmonary shunting, and ventilation-perfusion (/) mismatch. The causes may be classified by age, anatomic lesions, or abnormalities involving (1) lung and chest wall mechanics, (2) neuromuscular systems, and (3) central nervous system (CNS) control or respiratory drive. The presenting clinical findings usually help to determine the type of problem. Increased respiratory rate and effort (tachypnea and dyspnea) suggest mechanical problems with the lung or chest wall. Neuromuscular disease may result in progressively weaker respiratory efforts and eventually fatigue. CNS pathology may present as other neurologic features (coma, areflexia, weakness) and a variety of respiratory patterns, including bradypnea, apnea, and Cheyne-Stokes respirations. The heterogeneous group of pediatric diseases that can cause respiratory distress and failure requiring mechanical ventilation are discussed in Chapters 357 and 359 and Table 57–14 .

Pathogenesis.

Respiratory failure is the inability of the respiratory system to provide exchange of oxygen and carbon dioxide between air and blood, resulting in an impaired supply of oxygen and excretion of carbon dioxide to meet the body's metabolic demands. The physiology of respiratory function and gas exchange is discussed in Chapters 356 , 357 , and 359 . The oxygen absorption and carbon dioxide excretion that take place at the respiratory membrane occur because these two gases move along their respective concentration gradients, achieving complete equilibrium of pressure for each gas between the blood phase in the end capillary and the gas phase (air) with the alveolus. Inspired atmospheric room air has a P_{O_2} of approximately 159?mm?Hg, and gas inside the alveoli, the *alveolar air*, normally has a P_{O_2} of 104?mm?Hg. Alveolar air has this lower P_{O_2} because of humidification and because the oxygen in the alveoli is constantly being absorbed into the pulmonary blood. If the atmospheric air is supplemented with a higher concentration of oxygen, then the alveolar P_{O_2} (Pa_{O_2}) will be higher and the increased oxygen gradient between

SIRS	

CNS = central nervous system; SIRS = systemic inflammatory response syndrome.

Adapted from Helfaer M, Nichols D, Rogers M: Developmental physiology of the respiratory system. In Rogers MC (editor):Textbook of Pediatric Intensive Care, 2nd ed. Baltimore, Williams & Wilkins, 1992, pp 104–33.

alveolar air and pulmonary blood results in increased absorption of oxygen. Carbon dioxide diffuses through the respiratory membrane so quickly that the mixed venous and alveolar P_{CO_2} are nearly the same. Atmospheric air has a P_{CO_2} of approximately zero, and a healthy person's alveolar and venous P_{CO_2} is about 40?mm?Hg.

These relationships are described by the alveolar gas equation:

F_{IO_2} is the fraction of inspired oxygen—(e.g., breathing oxygen at room air with a concentration of 21%—an F_{IO_2} of 0.21). Pb represents the barometric pressure (assumed to be 760?mm?Hg at sea level), and PH_2O is the water vapor pressure (which dilutes the dry oxygen content of the atmosphere, about 47?mm?Hg). R represents the respiratory quotient, assumed to be 0.8, which can be calculated as follows:

Thus, the PaO_2 of a patient who breathes room air and has a Pa_{CO_2} of 40?mm?Hg would be predicted as:

If a patient were breathing a gas mixture with an F_{IO_2} of 0.5, then the P_{AO_2} would be 306?mm?Hg. The **alveolar-arterial oxygen gradient (A-a gradient)** is the difference between the predicted P_{AO_2} and the measured arterial P_{O_2} (Pa_{O_2}). This gradient is used to assess the severity of impairment of gas exchange. If a patient is breathing a gas mixture with an F_{IO_2} of 0.5 and has a Pa_{O_2} of 100?mm?Hg and a normal Pa_{CO_2} , the A–a gradient would be 206 (306 – 100). Comparing this with a normal A–a gradient of less than 10?mm?Hg (for healthy young subjects breathing air at sea level), it is clear that this child's gas exchange is impaired. An A–a gradient greater than 300?mm?Hg while breathing an F_{IO_2} of 1.0 signifies a serious oxygenation disturbance that may require mechanical ventilation.

Ventilation () is the amount of gas delivered to and exhaled from the lungs, and *perfusion ()* is the amount of mixed venous blood brought to the pulmonary capillary bed. The relationship between these two is referred to the */ratio*. This ratio is determined by the amount of pulmonary ventilation and perfusion, and optimal gas exchange occurs if they are distributed in the same proportion to each other throughout the lungs. Therefore, the normal /ratio = 1. There is a certain amount of nonuniformity in the distribution of ventilation and perfusion of normal lungs (see Chapter 357). Respiratory diseases may cause a spectrum of pathologic derangement from the normal matching of ventilation to perfusion, termed */mismatch*. Compensatory mechanisms by which the lungs attempt to restore / matching may not be adequate, potentially resulting in ventilated but nonperfused alveoli (/ = infinity) and/or perfused but nonventilated alveoli (/ = zero). Supplemental oxygen may improve the P_{AO_2} in patients with / mismatch.

Dead space ventilation occurs when the inspired gas is delivered to areas with no

perfusion. There is an obligatory amount of normal anatomic dead space because inspired gas must traverse the nose, nasopharynx, trachea, and larger conducting airways. However, alveolar (pulmonary) dead space occurs when alveoli are ventilated but not perfused. This results from a pathophysiologic process that impedes blood flow through the pulmonary capillary bed, such as pulmonary embolism, pulmonary hypotension, and obstructive lung disease.

The volume of gas entering and leaving the mouth or nose per breath is the tidal volume. Alveolar ventilation, the volume of air entering and leaving the alveoli per minute, is defined by the equation

Alveolar ventilation determines the rate of carbon dioxide excretion. Diseases that cause increased dead space result in decreased alveolar ventilation, and, unless the tidal volume or frequency of respiration increases enough to compensate, the Pa_{CO_2} will rise.

When the alveoli are perfused but not ventilated, this portion of lung acts as an *intrapulmonary shunt*, with mixed venous blood being shunted to the systemic arterial circulation without coming into contact with any inspired oxygen. This blood does not participate in gas exchange. The resultant increase in carbon dioxide content of the arterial blood is usually rapidly buffered so the effect on Pa_{CO_2} is negligible, but the dilution of oxygen content significantly lowers Pa_{O_2} . Therefore, diseases that cause increased intrapulmonary shunt cause hypoxemia. The hypoxemia associated with shunt can be severe and is often an indication for mechanical ventilation. Some examples of diseases increasing intrapulmonary shunting are acute respiratory distress syndrome, pneumonia, pulmonary hemorrhage, atelectasis, and pulmonary edema. Supplemental oxygen does not always enhance P_{AO_2} in patients with shunting.

Respiratory failure may also be classified as due to either lung disease or respiratory pump dysfunction (see Table 57–14). Lung diseases involve the airways, alveoli, or pulmonary circulation alone or in combination and result in hypoxemia. When lung disease leads to respiratory failure, patients have dyspnea, increased respiratory drive, and increased alveolar ventilation, which causes respiratory alkalosis unless the patient develops

---

fatigue leading to failure of the respiratory pump as well. The coordinated activities of the CNS and the respiratory muscles act like a respiratory pump; respiratory failure can result from CNS, neuromuscular, or muscular dysfunction. Failure of the respiratory pump causes hypoventilation, a decrease in alveolar ventilation, and hypercarbia. Hypoxemia may also occur when the respiratory pump fails; it is treated with supplemental oxygen or positive pressure ventilation.

Clinical Manifestations.

Children with impending respiratory failure due to lung disease have respiratory distress characterized by rapid breathing or *tachypnea*, exaggerated use of accessory muscles, and intercostal, supraclavicular, and subcostal *retractions*, which may be much more striking in a child than in an adult because of the increased compliance of the chest wall. Impending respiratory failure caused by respiratory pump dysfunction may be more difficult to recognize because these children may not have any signs of respiratory distress. A patient with a neuromuscular disease such as muscular dystrophy or Werdnig-Hoffman disease may be weak, and the degree of retractions may not be obvious. Other causes of respiratory pump failure, such as a narcotic ingestion or a brain tumor, cause decreased ventilatory drive and hypoventilation. An abnormally low respiratory rate or the shallowness of the breathing may identify these children.

Diagnosis.

Respiratory distress in children is usually diagnosed by history and physical examination; severe distress may need immediate treatment before performing diagnostic procedures or tests. Some patients may not tolerate procedures such as an arterial puncture for a blood gas determination or a radiologic study; a change into an uncomfortable position may make it more difficult to breathe. It may be best to leave the patient in the position of greatest comfort, provide supplemental oxygen by face mask, and use aerosolized treatments. If these measures are not tolerated and do not result in improvement, then endotracheal intubation is required to secure the airway (see Chapter 57.1).

Laboratory Findings.

Although the clinical presentation may require immediate intubation and mechanical ventilation, for the majority of children it is possible and helpful to first obtain an arterial blood sample to analyze blood gas tensions (Pa_{O_2} , Pa_{CO_2} , and pH) (see Chapters 48.8 and 359) and initiate noninvasive monitoring by pulse oximetry. Hypoxemic respiratory failure is defined as a Pa_{O_2} less than 60?mm?Hg with an F_{IO_2} greater than 0.6 (in the absence of cyanotic heart disease); hypercarbic respiratory failure is defined as an acute Pa_{CO_2} greater than 50?mm?Hg. In addition to analyzing blood gases, the decision to initiate mechanical ventilation should consider the cause of the respiratory failure, the possibility of reversing the cause of the failure via other interventions, and the overall trend in a patient's clinical status. A patient with respiratory pump failure from narcotic overdose may have an acute Pa_{CO_2} greater than 50?mm?Hg but should respond quickly to administration of a narcotic antagonist and may not require ventilatory support. Conversely, a patient whose lung disease results in hypoxemia and dyspnea that seem adequately treated with supplemental oxygen may have an initially lower than normal Pa_{CO_2} (respiratory alkalosis). However, if this patient tires, an acute rise in the Pa_{CO_2} may indicate impending respiratory failure even if the Pa_{CO_2} is still less than 50?mm?Hg.

Treatment.

Respiratory arrest or repeated apnea requires immediate respiratory support. Severe shock also may require mechanical ventilation, even if arterial blood gases are within acceptable range, because patients need increased oxygen delivery to vital organs. Patients in shock often have respiratory distress owing to metabolic acidosis; the work of breathing and some lactic acid production may be ameliorated by ventilatory

support. Acute neurologic compromise may require ventilatory support for inadequate or absent ventilation, for loss of protective airway reflexes (cough and gag), or for therapeutic hyperventilation. Intubation and airway management are discussed in Chapters 56 and 57.1 . Mechanical ventilation is discussed in Chapter 57.4.

57.4 Mechanical Ventilation (see also Chapter 357)

Lorry R. Frankel

Underlying Concepts and Terminology.

Positive pressure ventilators are the mainstay of providing mechanical ventilation in adult, pediatric, and neonatal ICUs. During positive pressure mechanical ventilation, the flow of gas during inspiration and exhalation is driven by the airway pressure gradient between the airway opening and the alveoli. Pressure may be administered at the airway opening by a tight-fitting mask connected to a ventilator—mask CPAP (continuous positive airway pressure); to a compressible bag attached to a gas source—bag-mask ventilation; or to both—mask BiPAP (bilevel airway pressure). In a PICU setting, ventilator support is most frequently provided by intubation of the trachea, with the placement of an endotracheal tube (ETT) and, on occasion, with a tracheostomy cannula. The ETT adapter, which attaches to the ventilator tubing, is considered the airway opening. During inspiration, the airway opening pressure is greater than alveolar pressure, thereby driving gas into the lungs and inflating them. Exhalation is usually passive and occurs because, at the end of inspiration, alveolar pressure becomes greater than airway pressure.

PRESSURES.

Peak inspiratory pressure (PIP) occurs during maximal inspiration. *Positive end-expiratory pressure* (PEEP) helps maintain the end-expiratory resting lung volume. Thus, the maximum pressure gradient is the difference between PIP and PEEP. The *mean airway pressure* is a measure of the average pressure to which the lungs are exposed during the respiratory cycle. Mean airway pressure can be increased by increasing PEEP, PIP, the ratio of inspiratory time to expiratory time (I:E ratio), or the inspiratory flow (Fig. 57–22). Adjusting the ventilator to

Figure 57.4-22 Five different ways to increase MAP: (1) increase inspiratory flow rate, producing a square-wave inspiratory pattern; (2) increase PIP; (3) reverse the inspiratory-expiratory (I/E) ratio or prolong the inspiratory time without changing the rate; (4) increase PEEP; and (5) increase ventilatory rate by reducing expiratory time without changing the inspiratory time. (From Harris TR, Wood BR: Physiologic principles. In Goldsmith JP, Karotkin EH [editors]: *Assisted Ventilation of the Neonate*, 3rd ed. Philadelphia, WB Saunders, 1996.)

increase mean airway pressure is the therapy for hypoxemia that is not responding to an increasing F_{IO_2} . This probably improves oxygenation by decreasing the number of collapsed alveoli or redistributing lung fluid.

COMPONENTS OF THE VENTILATOR BREATH.

Each complete ventilator breath has an allotted time for inspiration (I time) before the ventilator must cycle into exhalation time (E time). The sum of the I time and E time equals the allotted time per breath. The ventilator delivers a set number of breaths per minute, the *ventilator frequency*. The frequency determines the length of each breath. For example, a frequency of 20 would result in 3?sec/breath. Most ventilators allow setting either the I time or the *I:E ratio*. For example, if an I time of 1?sec is ordered and the breath is 3?sec, the I:E ratio will be 1?sec:2?sec. If an I:E ratio of 1:3 is ordered, then the I time would be 0.75?sec, and the E time would be 2.25?sec.

The change in lung volume during the inspiratory period is defined as the *tidal volume* (V_t). It is the volume above the *functional residual capacity* (FRC), that is, the volume above the end-expiratory lung volume. By convention, the gas flow is in units of L/min and the I time is in seconds; in pediatrics the V_t is usually expressed in milliliters rather than as fractions of a liter. From the alveolar gas equation, to adjust Pa_{CO_2} , either the V_t or the ventilator frequency is changed (see Chapter 57.3).

PRESSURE-CONTROLLED VS. VOLUME-CONTROLLED VENTILATION.

These are the two primary forms of positive pressure ventilators (Box 57–5). Pressure-controlled ventilators allow a clinician to set the PIP and PEEP. The increase in airway pressure occurs swiftly at the initiation of inspiration to achieve the set PIP. This PIP is then maintained throughout the I time. In pressure-controlled ventilation, the lung volume rises until it reaches its capacity at that PIP or until the ventilator cycles into exhalation. Thus, V_t is not set but rather is determined by both the pressure gradient of the ventilator and the pulmonary mechanics of the patient. In volume-controlled ventilation, the V_t is preset as a product of setting flow and I time. The airway pressure rises throughout inspiration and reaches its peak when the entire V_t has been delivered. Thus, PIP is not set but rather is determined by both the V_t and the pulmonary mechanics of the patient.

VENTILATOR-PATIENT INTERACTIONS.

When children are not attempting to breathe spontaneously, the ventilator completely controls the respiratory pattern. For children who can attempt to breathe, the degree to which a ventilator is able to synchronize with the patient's own respiratory efforts may have significant clinical effects. Patients whose lung disease is

Box 57.4-5. Comparison of Pressure-Controlled and Volume-Controlled Ventilation

PRESSURE-CONTROLLED VENTILATION

- Constant pressure delivered
- Variable volume delivered; reduced risk of barotrauma
- Changes in patient's compliance or resistance may lead to alterations in delivered volumes as pressure remains constant
- Changes in tidal pressures may result in changes in minute ventilation

VOLUME-CONTROLLED VENTILATION

- Constant volume (V_t) delivered; less risk of hypoventilation or hyperventilation
- Variable pressure (PIP) delivered
- Changes in patient's compliance or resistance leads to potential for dangerously high inflating volume delivered (requires closer monitoring of tidal volume and carbon dioxide, as well as pressure alarms)

VT = tidal volume; PIP = peak inspiratory pressure.

improving and who thus are receiving less sedation in an attempt to wean from ventilator support may find that when they need to, they are unable to draw a breath, thereby experiencing dyspnea. Patients also may experience anxiety as gas is pushed into their airway while they are trying to exhale. This dyssynchrony often necessitates pharmacologic interventions with sedation or paralytic agents, which may result in prolonged intubation and ventilation. Patient-ventilator dyssynchrony

may also cause barotrauma or pressure injury to the lungs. Advances in mechanical ventilation have attempted to improve patient-ventilator synchronization.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION (SIMV).

SIMV allows better response by the ventilator to the patient. During SIMV, the ventilator allows the child to trigger a breath by spontaneously attempting to inspire (Fig. 57–23). If the patient takes too long to initiate a spontaneous breath, then inspiration is time triggered by the ventilator: a mandatory breath. Ventilator frequency determines the total time allotted per breath, and some percentage of that time is the window allowed for the patient to initiate inspiration. If the patient does not spontaneously try to breathe during this window of time, then the ventilator initiates inspiration. SIMV may be either volume controlled or pressure controlled. A patient may also breathe spontaneously more often than the set frequency of SIMV inspiring fresh gas from the circuit at the set PEEP, but these breaths are not assisted by a ventilator breath.

SIMV does not allow for complete spontaneous ventilation. Patients trigger inspiration, but they cannot control when inspiration ends and the ventilator cycles to expiration. Patients cannot control the I time of the ventilator-assisted breaths, even though they can control the I time of the nonassisted breaths in between. The *pressure support mode* allows for spontaneous breathing by patients. The ventilator assists every breath a child initiates by applying a predetermined amount of airway pressure above the set PEEP. A child can control the rate of breathing and the duration of inspiration, so the breathing pattern may truly be called spontaneous. Many ventilators allow both

Figure 57.4-23 Synchronized intermittent mandatory ventilation (SIMV). At set intervals, the ventilator's timing circuit becomes activated and a timing “window” appears (*shaded area*). If the patient initiates a breath in the timing “window,” then the ventilator delivers a mandatory breath. If no spontaneous effort occurs, then the ventilator delivers a mandatory breath at a fixed time after the timing “window.” (From Banner MJ, Gallagher TJ: Respiratory failure in the adult: Ventilatory support. In Kirby RR, Smith RA, Desautels DA [editors]: *Mechanical Ventilation*. New York, Churchill Livingstone, 1985.)

pressure support and SIMV. The pressure support breaths can occur whenever a child attempts to inspire, unless the patient is breathing within that window of time that results in an SIMV breath.

MONITORING AND ALARMS.

What is not controllable is monitored. In pressure-controlled ventilation, the V_t is monitored. In volume-controlled ventilation, the airway pressure is monitored; safety precautions include pop-off limits to the peak airway pressure. An oxygen analyzer allows monitoring of F_{IO_2} .

Alarms can be set for a wide array of events. The common alarms are for high or low airway pressure, absence of flow (apnea), loss of electrical power, high or low exhaled V_t, and high or low minute volume. When alarms occur, they must then be evaluated to determine if there is a malfunction of the ventilator or a change in the patient. The importance of frequent physical examination cannot be overemphasized; it is the fastest means of diagnosing a variety of ventilator problems, such as patient-ventilator dyssynchrony, ETT obstruction, barotrauma pneumothorax, and accidental extubation.

Approach to Mechanical Ventilation.

The pressure gradient that inflates the lungs must overcome the pulmonary mechanics of the patient's respiratory system. See Chapter 357 for discussion of compliance, resistance, and time constant of the respiratory system. Respiratory diseases result in decreased lung compliance or increased airway resistance or both. Ventilator strategies are designed to ameliorate physiologic derangements and resulting ventilation-perfusion mismatch.

DISEASES OF DECREASED COMPLIANCE.

Compliance is decreased in various diseases that affect the lung parenchyma, such as acute respiratory distress syndrome (ARDS), atelectasis, pneumonia, pulmonary edema, and pulmonary hemorrhage. In all of these diseases, FRC is reduced as terminal air spaces are flooded or collapsed, owing to the presence of abnormal fluid within the alveoli or atelectasis from the decreased amount of surfactant lining the alveoli. These smaller alveoli are more difficult to inflate. Intrapulmonary shunt is increased when blood flows to poorly ventilated lung units. One goal of mechanical ventilation when lung compliance is decreased is to decrease shunting by improving ventilation to the perfused lung units. The ventilator approach to decreased FRC is to increase mean airway pressure in order to recruit atelectatic areas of lung; this increase is usually achieved by higher PEEPs, although higher PIPs also increase mean airway pressure (see Fig. 57–22).

Decreased compliance requires a higher pressure gradient to achieve a given (V_t). This means that with volume-controlled ventilation, the PIP will be higher than it would for a patient with normal lungs. If the ventilator is pressure controlled, then a given PIP may result in a V_t that will be lower than that of a patient with normal lungs. Diseases that decrease compliance also may respond to higher ventilator rates as the lungs empty and fill more quickly. If neither ventilator pressure nor rate is increased sufficiently to compensate for decreased compliance, then hypercarbia develops.

DISEASES OF INCREASED RESISTANCE.

Resistance is increased in various diseases that decrease the caliber of the airway lumen by edema, spasm, or obstructing material. Because airways decrease in caliber during exhalation, increased resistance affects expiratory flow more than inspiratory flow. Diseases in which airway resistance is increased include asthma, bronchiolitis, bronchopulmonary dysplasia, smoke inhalation, and cystic fibrosis.

Diseases of increased resistance are often accompanied by both increased intrapulmonary shunt and dead space ventilation. Shunt occurs if the increased

resistance greatly impedes gas flow, decreasing ventilation to alveoli that remain perfused. Dead space ventilation occurs if the increased resistance leads to gas trapping in areas of the lung that contain hyperinflated alveoli. These areas of hyperinflated lung units exert pressure on the surrounding structures, and this results in a reduction of pulmonary capillary blood flow. The increases in both shunt and dead space mean that these diseases produce both significant hypoxemia and hypercarbia. Increased resistance requires that a higher pressure must occur for the flow of gas to reach the terminal air sacs. Therefore, if volume-controlled ventilation is used, an increase in PIP is required to deliver a given V_t. If pressure-controlled ventilation is used, tidal volume is lower than in a normal lung at the same pressure.

Increased resistance may result in significant increases in time constant (see Chapters 355 and 357), unless there is a proportional decrease in compliance, which rarely happens in diseases of increased resistance. A longer time constant (time necessary for gas to fill or empty the alveoli) necessitates long inspiratory and expiratory times. Therefore, these lung diseases may be adversely affected if the ventilator frequency is too high and the expiratory and inspiratory times are too short. This results in a phenomenon known as gas trapping as the ventilator cycles back into inspiration before the lung has had sufficient time to empty. The ventilator breaths stack on each other as more and more gas is trapped, resulting in an increase in the FRC. This eventually leads to lung hyperinflation, a predisposition to pneumothorax and chronic barotrauma, and reduction in compliance.

INITIAL SETTINGS.

Mechanical ventilation is initiated to provide support for lungs that function normally or for diseases of decreased compliance, or of increased resistance (Table 57–15). *For supporting normal lungs*, ventilator frequency may be slightly lower than the normal respiratory rate for age because ventilator V_t is usually set higher than a healthy person's V_t of 5–7?mL/kg. The customary range for ventilator V_t has been lowered to 8–10?mL/kg from 10–15?mL/kg. For pressure-controlled ventilation, an initial PIP of 20–25 H_2O is usually sufficient to move an adequate V_t, but this must be immediately assessed by observation of chest expansion and measurement of V_t.

To initiate *support for diseases of decreased compliance*, mean airway pressures need to be higher. A higher PEEP is often used to achieve this. PEEP is titrated upward in an attempt to provide adequate oxygenation at an F_{IO_2} less than 0.6. If volume-controlled ventilation is used, the PIP may be much greater than for normal lungs, and clinicians must pay close attention to pressure alarms. If pressure-controlled ventilation is used, the initial PIP may need to exceed 30?cm H_2O. The V_t has to be closely monitored. Significant hypoxemia results from these diseases, and it is customary to start with an F_{IO_2} of 100% and then reduce it as one attempts to avoid oxygen toxicity. The ventilator frequency may be set higher than normal because a decreased time constant permits a faster rate. A common inspiratory time is 0.8–1?sec.

Diseases of increased resistance often have very high time constants. Ventilator frequency may need to be set as low as 12–16 breaths/min in severe status asthmaticus to allow adequate inspiratory and expiratory times. It is also customary to try to minimize PEEP to 2–3?cm H_2O in these diseases to minimize risk of gas trapping.

COMPLICATIONS.

There are many pulmonary and systemic complications of mechanical ventilation. Lung injury may result from positive pressure (*barotrauma*), *oxygen toxicity*, or excessive volume changes in the lung—volutrauma. Volutrauma may be manifested acutely as pulmonary air leak, such as pneumothoraces, pneumomediastinum, pulmonary interstitial emphysema, and bronchopleural fistula. Volutrauma may also be a cause of chronic repetitive lung injury, exacerbating the primary disease. This may result from subjecting alveolar units to repeated overdistention, such as with excessive V_t, or to cyclic collapse and re-expansion, such as with insufficient PEEP to stabilize the resting lung volume. In diseases of decreased compliance, the lung units of higher compliance may receive more of the V_t than the less compliant units, leading to volutrauma of the

---

TABLE 57.4-15 -- **Guidelines for Initiating Mechanical Ventilation**

	Normal Lungs	Decreased Compliance	Increased Resistance
Tidal Volume (V_T)	8–12?mL/kg (set of volume-controlled and derived if pressure-controlled ventilation)	10–12?mL/kg (may need to use less if the inflating pressures are too high; i.e., risk for volutrauma)	10–12?mL/kg (may need to use less volume if the inflating pressures required are too high; i.e., barotrauma)
Rate (breaths/min)	Physiologic norm for age or lower (depending on the V_T used; e.g., infant rate = 30, toddler rate = 20, adolescent rate = 16)	May require higher rates to maintain adequate minute ventilation	Often requires lower rates to allow adequate emptying time
Peak Inspiratory Pressure PIP (cm H_2O)	Initial PIP = 20–25?cm H_2O; monitor for adequate chest expansion and V_T	May require higher PIP to obtain acceptable V_T	May require higher PIP to obtain acceptable V_T

Positive End-Expiratory Pressure (PEEP)	2–4?cm H_2O to prevent atelectasis	Frequently requires higher PEEP to achieve oxygenation and improved compliance (e.g., 6–10?cm H_2O) Anticipate decreased venous return and cardiac output	May need to maintain low PEEP to avoid exacerbation of gas trapping and overinflation
Oxygen Concentration (FIO_2)	May not need supplemental oxygen; however, one usually begins with FIO_2 of 1.0 and may then quickly wean to an FIO_2 =0.5	Begin with an FIO_2 of 1.0 Attempt to wean to =0.6 by adjusting mean airway pressure/PEEP	Begin with an FIO_2 of 1, wean to maintain adequate oxygenation and avoid oxygen toxicity
Inspiratory Time (I time)	Normal for age I:E = 1:2, 1:3	Generous I time to allow recruitment of collapsed lung segments (e.g., 1:1.2)	Ensure adequate I time and E time, especially E time, to avoid gas trapping (e.g., I:E of 1:3 or 1:4)

healthier segments of lung. This mechanism may contribute to the chronic lung injury that can develop in ARDS. In diseases of increased resistance, the lung units with higher resistance need more time to fill and empty. This leads to overfilling of the lung units with lower resistance and time constants and to gas trapping and overdistention of the alveoli in the high time constant units with severely obstructed airways.

Positive pressure ventilation also may have effects on the cardiovascular system. Some portion of the mean airway pressure is transmitted through the lungs and raises intrathoracic pressure. This may impede venous return and decrease right ventricular filling. Elevated intrathoracic pressure also may compress the pulmonary circulation and increase the afterload on the right ventricle, which may cause the interventricular septum to shift toward the left ventricle, resulting in a decrease in volume of the left ventricle and a reduction in left ventricular stroke volume. Cardiac output may thus be impeded. Alternatively, elevations in intrathoracic pressure may cause an afterload reduction for the left ventricle. The net result of these many cardiovascular effects may be beneficial or detrimental, depending on the overall cardiovascular status of the child. In general, high mean airway pressures require close observation for possible hemodynamic compromise and may necessitate support with fluids and inotropic drugs (see Chapter 57.2).

An ETT may become obstructed owing to mucus, purulent material, or blood from trauma to the airway or from the child biting on the tube. These are immediately life-threatening complications. An ETT also may cause injury to the tracheal mucosa, resulting in subglottic stenosis, which is usually not symptomatic until the tube is removed. Subglottic stenosis may resolve with time or may ultimately require surgical intervention (see Chapter 373).

Prolonged intubation and mechanical ventilation may predispose the child to nosocomial infections, often by bacteria with resistance to numerous antibiotics. Nosocomial infection, sepsis, and other organ system failures are the leading cause of death of patients with respiratory failure.

Other approaches to the care of the critically ill child with acute respiratory failure include high-frequency modes of ventilation (HFV), the application of permissive hypercapnia, and the use of prone positioning. HFV can be divided into three distinct groups: oscillatory, jet, and flow interruption. All three modes of ventilation utilize very small tidal volume (<1?mL/kg), very rapid rates (150–1,000 breaths/min), and lower mean airway pressures used to provide a gentler form of mechanical ventilation. *Permissive hypercapnia* allows the patient's Pa_{CO_2} to rise into the 60–70?mm?Hg range as long as the patient is adequately oxygenated (Sa_{O_2} > 92%) and the patient is able to tolerate the degree of acidosis. This is used to limit the amount of barotrauma and volutrauma to the patient. Positioning the patient in the prone position has been shown to improve oxygenation and reduce ventilator-induced lung injury in patients with severe lung injury; outcome may not be improved.

57.5 Renal Stabilization

Joseph V. DiCarlo

Etiology and Epidemiology.

Renal function is often significantly affected by critical illness that does not involve intrinsic renal disease. Renal dysfunction to some degree is frequently encountered but may be of little consequence or may contribute to the multiple organ dysfunction syndromes. Renal failure in children is most commonly caused by shock, sepsis, hypoxia, or nephrotoxic medications (see Chapter 527). Severe congenital heart disease is a risk factor for life-threatening renal cortical and medullary necrosis resulting from renal ischemia. In infants with renal hypoperfusion and ischemic injury, 50% may have congenital heart disease, 30% may have asphyxial shock or sepsis, whereas only 2% may have gastroenteritis with dehydration. There is usually little association between the renal lesions

and the use of radiographic contrast medium. Although renal failure rarely occurs after gastroenteritis and dehydration in children, it can occur as a consequence of hemolytic-uremic syndrome (see Chapter 510) or can be associated with renal vein thrombosis. Renal insufficiency or failure associated with hepatic failure (the hepatorenal syndrome) may also require intensive care. Obstructive uropathy is a potential cause of renal failure necessitating PICU admission. Oliguria may also be caused by excessively high intra-abdominal pressures (abdominal compartment syndrome). Reducing the pressure improves urine output.

Strategies to Improve Renal Function.

Although oliguria is common in the PICU and may be associated with poor outcomes, often only additional fluids or low doses of diuretics are needed for correction. In patients with oliguric renal failure, adequate intravascular fluid volumes estimated by the heart rate (within 20% of normal for age) and central venous pressure (at least 4–9?cm H_2O) should be maintained. In addition to treating the underlying cause, loop diuretics may be helpful.

Loop diuretics are commonly used to improve fluid balance in critically ill children. However, tolerance to the effects of the diuretic may require large bolus doses, intravenous drips, a combination of diuretics, or changing drugs. Some children who demonstrate little effect from furosemide respond to bumetanide. Continuous infusion of loop diuretics may decrease dosage requirements, improve response, and minimize adverse effects. Loop diuretics are often used in the hope of decreasing lung water in children with capillary leak syndrome (e.g., ARDS, septic shock), but the effect is often modest. The pairing of a loop diuretic with an infusion of albumin is probably efficacious only in the nephrotic syndrome.

Use of a single loop diuretic may soon lead to drug tolerance owing to hypertrophy of the distal nephron and concomitantly enhanced sodium reabsorption. Resistance can be overcome by the addition of metolazone or thiazides to block distal sodium reabsorption.

In the rare instance that renal failure is caused by (or is impending from) a circulating nephrotoxin or substance that might obstruct the renal tubules (e.g., myoglobin), *forced diuresis* may be beneficial. Crystalloid is infused at up to two times the maintenance rate, followed by mannitol (0.5?g/kg) and/or furosemide (0.5?mg/kg) every 4?hr. However, high infusion rates pose the risk of pulmonary edema, and mannitol may cause osmotic tubular kidney damage if allowed to crystallize in the interstitium.

Vasoactive Medications and Renal Preservation.

Although vasopressor agents can theoretically reduce renal blood flow by causing vasoconstriction, renal blood flow and function usually improve when renal perfusion pressure is increased during shock by the infusion of vasopressors. Dopamine at doses of 1–3?µg/kg/min often improves urine output and natriuresis, probably as a result of a direct effect on renal tubules and splanchnic dilatation. However, little evidence shows that dopamine prevents acute renal failure or improves patient outcome. Norepinephrine when used to increase the blood pressure in patients with shock may increase renal blood flow and improve renal function. Early and rapid restoration of the circulating blood volume is probably most efficacious in preserving renal function in shock.

***Renal Replacement Therapies* (see Chapters 527 and 528).**

Continuous venovenous hemofiltration (CVVH) is the modality of choice for renal replacement therapy in critically ill children (see Chapter 59). Hemofiltration is usually performed through double-lumen venous catheters, with circulation through the circuit affected by a blood roller-pump fitted with an air trap. CVVH is usually more appropriate than conventional hemodialysis in unstable patients because lower blood flows are needed (usually 10?mL/kg/min) and the membranes used may be more biocompatible than the standard hemodialysis membrane. The circuit is best anticoagulated by infusing a citrate solution into the filter; the resultant hypocalcemia is counteracted by a calcium infusion for the patient. Reasonably high clearances can be obtained during continuous hemodialysis or hemodiafiltration, even in severely catabolic, septic patients. Countercurrent dialysate flow improves clearance rates, and well-designed replacement solutions can correct acidosis and electrolyte imbalances. CVVH may be beneficial in the management of systemic inflammation (e.g., in septic shock or acute respiratory distress syndrome). The filter removes all substances below a molecular weight of 17,000 daltons that are not protein bound; many pro-inflammatory substances are of this size or smaller. Clearance is best

achieved by production of 1 to 4?L of ultrafiltrate per hour.

57.6 Nutritional Stabilization

Joseph V. DiCarlo

Critically ill children need nutritional support to ameliorate negative nitrogen balance resulting from excessive catabolism (Tables 57–16 and 57–17 , Fig. 57–24) (see Chapter 42). Carbohydrate (glucose infusion of 3–5?mg/kg/min) is given to inhibit the breakdown of endogenous protein. Generally, 70% of calories should be derived from carbohydrates and 30% from lipids. It is often difficult to deliver adequate calories to critically ill children because of enteral intolerance or restrictions in fluid volumes, but the caloric goals should be attainable within the first week of hospitalization.

Amino acids should be provided in reasonable amounts, in any form (1.5?g/kg in older children, 2.0?g/kg in infants). Adequate amounts of glutamine, alanine, and the essential amino acids should be included, but branched-chain amino acids (leucine, cysteine, valine, and lysine) may not confer any special benefit.

Vitamins, particularly water-soluble vitamins B complex and C, are best administered enterally. Vitamin deficiencies, however, can develop even in children receiving parenteral nutrition (e.g., thiamine deficiency leading to Wernicke encephalopathy and riboflavin deficiency).

Essential minerals and trace elements including zinc, magnesium, and selenium should also be provided.

TABLE 57.6-16 -- **Caloric and Protein Requirements in the Critically Ill Child**

Critical illness	25–30?kcal/kg/24?hr
Mechanical ventilation	20–25?kcal/kg/24?hr
Receiving growth hormone	15–20?kcal/kg/24?hr as carbohydrate
Burn or trauma	40–45?kcal/kg/24?hr
Protein	1.5–2.5?g/kg/24?hr
Protein (burn >20%)	2.0–3.0?g/kg/24?hr

TABLE 57.6-17 -- Relative Effects of Starvation and Hypermetabolism

From Wesley JR: Nutrient metabolism in relation to systemic stress response. In Pediatric Critical Care. Furhman BP, Zimmerman JJ (editors): CV Mosby, St. Louis 1998. Adapted from Barton R, Cerra FB: Chest 1989;96:1153.

Rarely, growth factors are administered, especially growth hormone. Growth hormone may be beneficial to debilitated children having difficulty in weaning from mechanical ventilation. However, growth hormone aggravates the insulin resistance

Figure 57.6-24 Index of per cent change in metabolic activity caused by various types of stress. (From Wesley JR, et al: *The University of Michigan Hospitals Parenteral and Enteral Nutrition Manual*, 6th ed. Chicago, Abbott Laboratories Hospital Products Division, 1990.)

and hyperglycemia common to critically ill children and produces increased mortality in critically ill adults. Intensive insulin therapy (maintaining blood glucose levels between 80 and 110?mg/dL) has been shown to reduce morbidity and mortality in adults in a surgical ICU. This has not been studied in children.

Enteral Feeding.

Early enteral feeding in critically ill children, particularly those with sepsis, may avert ulcerative complications, preserve the indigenous intestinal flora, avoid overgrowth by pathogens, and prevent atrophy of the mucosa. Normal flora also may be restored, in part, by the administration of acidophilus. If the stomach is relatively atonic, early feeding may be accomplished through a weighted tube passed through the pylorus into the jejunum; fluoroscopic guidance or placement via endoscopy may be necessary. However, patients with sepsis often have ileus that precludes enteral nutrition but resolves with time (3–7 days).

Parenteral Nutrition.

If the gastrointestinal tract cannot be used, parenteral nutrition is necessary. Conversion of maintenance intravenous fluids to parenteral nutrition is often indicated by the 2nd or 3rd day of hospitalization. There is no need to administer amino acids gradually, although protein restriction may be indicated for renal failure.

Overfeeding.

Excessive intake of carbohydrates is manifested as hyperglycemia, which may result in hyperosmolarity, osmotic diuresis, and dehydration. Subsequently, increased carbon dioxide production and an increase in the respiratory quotient may tax an already compromised respiratory system. Excessive administration of lipids can produce hypertriglyceridemia and fatty liver and may increase the risk for infection.

Immunomodulation through Diet.

Unfed patients in the PICU, in general, have the highest complication rate. Attempts to enhance immune function through dietary supplementation with glutamine, arginine, omega-3 fatty acids, and nucleotides have failed to demonstrate benefit.

57.7 Neurologic Stabilization

Joseph V. DiCarlo
Lorry R. Frankel

Acute neurologic deterioration may be a life-threatening event with numerous causes and a few typical clinical presentations (coma, seizures, weakness, altered mental status). The clinician must act quickly to stabilize the child with an evolving neurologic picture to quickly reverse the process and avoid further permanent injury to the brain. The initial event produces the "primary injury" to the brain that gives rise to the typical signs and symptoms. Failing to recognize the primary events from the clinical manifestations, the child may be at significant risk for further injury referred to as "secondary injury." This is related to systemic hypotension, respiratory failure, and hypoxia as well as progressive cerebral or brainstem herniation resulting from the development of cerebral edema or intracranial bleeding, which if unrecognized and untreated worsen the outcome for the child.

Preservation of global neurologic function, prevention of secondary cerebral edema, and optimizing regeneration are important particular concerns to the intensive care physician. Several disease states can temporarily or permanently profoundly affect

neurologic function. The intensivist must recognize states that have the potential for permanent dysfunction and support the child in ways that optimize return toward normal. The most common causes of acute global neurologic dysfunction in children are head trauma, hypoxia-ischemia, central nervous system (CNS) infection, and encephalopathies from endogenous metabolites or exogenous toxins. Idiopathic status epilepticus can also cause a moderate or severe encephalopathy. Global neurologic dysfunction coupled with focal signs may be a late presentation of a CNS tumor or abscess.

The manifestations of an acute or evolving neurologic pattern can produce generalized or focal findings. Coma, stupor, and lethargy are more general findings suggestive of an advancing process that has global cerebral implications. Focal findings may reflect a more well-defined process localized to one part of the brain. *Coma* refers to a state in which the patient is unable to arouse or respond to noxious stimuli and is completely unaware of self and surroundings. *Stupor* may be confused with normal sleep, but the patient can be aroused with painful stimuli. *Lethargy* is more subjective and is used to indicate drowsiness or decreased wakefulness. These patients may be more confused but are able to communicate. Because these

terms are often used by different physicians with different meaning, it is best to record the physical findings and the Glasgow Coma Scale (GCS) score (see Table 57–3).

Head Trauma.

Traumatic brain injury (TBI) is the primary injury that is caused by the direct mechanical disruption of brain tissue and the subsequent secondary injuries that result from the various cerebral and systemic processes worsened by events in the post-traumatic period. TBI in children is different than in adults because of the unique pathophysiology of children associated with the epidemiologic characteristics of pediatric injury. The causes of TBI in children can be separated into injuries associated with child abuse, contact injuries, and inertial injuries.

Nonaccidental trauma, or child abuse, has been thought to produce primary brain injury from repetitive acceleration-deceleration forces, which accompany shaking (therefore the term "shaken baby") (see Chapter 35). The injuries sustained may be more compatible with hypoxic injury secondary to brain- stem and spinal injury or the direct effects of the traumatic force. Victims of child abuse may not have signs of external trauma (e.g., bruises, fractures). Instead, they may present with mental status changes (lethargy or irritability), poor feeding, apnea, or seizures. If nonaccidental trauma is suspected, the clinician must obtain a head CT scan to evaluate for acute and subacute injuries such as subdural and epidural hematomas or effusions, punctate intracerebral hemorrhages, skull fractures, cerebral edema, atrophy, and/or hydrocephalus.

Contact injuries occur when an object strikes the head. The force generated by the impact may result in a skull fracture (depressed or linear), cerebral contusion (both coup and contrecoup), or intracranial bleeding (epidural hematoma, subdural hematoma, subarachnoid hemorrhage, or deep intracerebral hematomas). In severe forms of contact injuries, all of aforementioned findings may exist. Those with severe intraparenchymal and intraventricular hemorrhages have a poorer prognosis. In addition, diffuse cerebral edema may develop; this is not always evident on presentation and is not always associated with the severity of the trauma.

Inertial injuries usually occur from rapid acceleration-deceleration forces. This mechanism of injury results from the movement of the intracranial structures within the cranial vault. This may produce severe forms of microscopic injury to the axons resulting in diffuse axonal injury (DAI). Inertial injuries may occur in isolation or in association with contact injuries. The clinical significance of DAI is dependent on the extent and location within the brain. DAI of the brainstem may have more serious consequences than DAI in other parts of the brain.

Secondary brain injuries associated with trauma may occur in the immediate post-traumatic period or develop over the next several days. Secondary injury is associated with systemic hypotension, hypoxia, intracranial hemorrhages, or increased metabolic needs. Cerebral edema is a significant secondary injury that may lead to further neuronal damage, cerebral herniation, and death. TBI may also produce events that may lead to neuronal death via the release of a variety of mediators such as excitatory amino acids (EAAs). This occurs after a generalized depolarization of neurons following the primary brain injury. When this happens, there appears to be cerebrovascular dysfunction (loss of autoregulation), cerebral edema, alterations in the blood-brain barrier, release of free radicals, damage to the mitochondria, apoptosis, and neuronal death.

Children with traumatic head injury may take a long time to recover but often regain significant function during rehabilitation.

Hypoxia-Ischemia.

Encephalopathy from poor or absent cerebral perfusion (thus both hypoxia and ischemia) often heralds a poorer outcome than that from trauma; the physician has little to offer to improve the outcome. Often there is diffuse, global brain injury. These children may have experienced a period of asystole and have required cardiopulmonary resuscitation (CPR) such as after near-drowning episodes, acute life-threatening events, smoke inhalation, upper or lower airway obstruction, shock, electrical injuries, and other life-threatening events. The lack of oxygen and perfusion produces primary neuronal damage. Secondary injury occurs from the response of the activation of mediators, which activate a cascade of events that result in cerebral edema and apoptosis and cell death.

Imaging studies may be helpful in evaluating the structural damage seen with hypoxic-ischemic encephalopathy. These changes may not be immediately apparent; they provide an insight into the extent of the cerebral injury. Rapid diffusion weighted imaging MRI demonstrates lesions faster than any other imaging modality. There is often preservation of the brain- stem function. Other organ systems may reflect hypoxic-ischemic injury such as the liver, kidneys, intestines, and heart. A poor prognosis is associated with a GCS score of 3, hypotension, cerebral edema, persistent apnea requiring CPR for more than 25?min, persistent loss of cranial nerve reflexes (e.g., corneal), and coma for more than 24?hr. Those patients who have required significant support for these other organ systems have very poor outcomes. Children who have sustained serious hypoxic-ischemic brain injury but have preserved other vital organ function (respiration, blood pressure, pulse) may survive with severe neurologic function and possibly in a persistent vegetative state.

CNS Infection.

CNS infections include meningitis, meningoencephalitis, encephalitis, subdural or epidural empyema, and brain abscess. Viruses and bacteria cause meningitis; fungal infections may be noted in patients undergoing transplantation and its inherent requirement for immunosuppression. Important treatable causes for stupor and coma include bacterial meningitis, herpes encephalitis, bacterial abscess, cerebral toxoplasmosis, and tuberculous meningitis. An infectious cause must be considered in any patient with an acute neurologic deterioration associated with fever or leukocytes or in those without a history of trauma. There may or may not be signs of meningeal irritation such as nuchal rigidity or Kernig and Brudzinski signs. Infants may not always have a bulging fontanel. Patients may also present with global encephalopathy such as coma or with status epilepticus.

Early diagnosis and treatment with appropriate antibiotics or antiviral drugs are important. If the patient demonstrates any manifestations of systemic complications (hypotension, apnea) the clinician must address these immediately to prevent secondary neuronal injury and other organ dysfunction. This includes airway

management, mechanical ventilation, and cardiovascular

support. Complications from acute neurologic infections include cerebrovascular infarcts, cerebritis, cranial nerve compression, development of hydrocephalus, subdural effusion, cerebral edema, and herniation. These findings are detected with imaging studies, which should be performed if the patient is not improving within 24–48?hr or whose condition begins to deteriorate with the development of focal findings or signs of increased intracranial pressure (ICP) (hypertension, bradycardia, irregular respirations, or signs of third or sixth cranial nerve compression). Neurosurgical consultation may be indicated if there is a surgical complication.

Encephalopathies from Endogenous Metabolites or Exogenous Toxins.

Profound encephalopathy may result from metabolic defects (inborn errors of metabolism producing hypoglycemia, hyperammonemia, lactic or organic acidosis), from fulminant hepatic failure (hyperammonemia plus other unmeasured neurotoxins), or from the ingestion of certain drugs and substances (ethanol, anticonvulsant drugs). Accidental ingestions are very common in toddlers and young children. Older children may experiment with various chemical substances or ingest wild mushrooms, which may produce acute cerebral signs. Any patient who has an altered level of consciousness without a clear explanation should have a drug toxicology screen.

Other laboratory tests may be helpful in the assessment of the child who presents with obtundation. These tests include routine electrolytes to evaluate for an increased anion gap (acidosis from endogenous acids or exogenous acids such as salicylates), serum osmolarity to detect for differences between calculated and measured osmolarity (alcohol, ethylene glycol ingestion), and arterial blood gas analysis to evaluate respiratory status to determine if there is either a respiratory alkalosis (early salicylate poisoning or hyperammonemia), respiratory acidosis (opiate or barbiturate ingestion producing respiratory depression), or a metabolic acidosis (late salicylate ingestion or endogenous lactic or organic acidosis).

One must always determine if there are alterations in glucose homeostasis because hypoglycemia will produce obtundation, stupor, and coma. Hypoglycemia occurs frequently as a result of various metabolic and endocrine disorders and with intoxication with alcohols. Young infants and children are especially prone to episodes of hypoglycemia because they have limited glycogen stores and can become seriously hypoglycemic as a result of prolonged fasting, inborn errors of metabolism, hyperinsulinism, liver failure, or ingestions. Hypoglycemia is easily reversible and should be aggressively pursued in every comatose child.

Diabetes Mellitus.

Severe cerebral edema may occur during treatment of diabetic ketoacidosis (DKA). The cause for such edema is likely due to the action of “idiogenic osmoles,” osmotically active particles (e.g., inositol) formed within the cerebral cells during the acute phase to counteract the effects of hyperglycemia. If serum osmolality declines too quickly, these osmolar particles act to attract water into the cell. Cerebral edema in DKA may be associated with significant morbidity and mortality. Coma may also occur in severe DKA or when associated with severe hyperosmolar states before treatment (see Chapter 583). Hyperglycemia and a lactic acidosis (without ketonuria) are common during the hypoxic-ischemic encephalopathy and have a poor prognosis.

Status Epilepticus.

Severe status epilepticus will result in stupor or coma and has the potential for permanent cellular damage if the seizures are prolonged or associated with hypoxia, hypercarbia, and hypotension (see Chapter 586). Seizures lasting more than 10?min must be treated aggressively. Intensive therapies are aimed at halting epileptic activity and reducing neurologic cell metabolism in order to limit the extent of the primary neuronal injury. Electrical status may severely affect the brain in the absence of clinically evident seizures; an electroencephalogram will confirm the diagnosis.

Intracranial Hypertension.

Acute intracranial hypertension often initially presents first with headache and confusion but may advance at various rates through combativeness, somnolence, and coma. It may be seen as a complication of either global or focal encephalopathies or mass lesions. An increase in the volume of cerebral contents within the rigid cranial cavity (blood, edema, masses, cerebral [ventricular] spinal fluid) produces an increase in ICP. This may result from trauma from hemorrhage or hyperemia; hydrocephalus with cerebrospinal fluid accumulation; tumors or abscesses; severe CNS infections; and metabolic aberrations, including hypoxia-ischemia. As the ICP increases, the effective cerebral perfusion pressure (CPP) decreases (see Chapter 55). CPP is equal to the mean arterial pressure minus the ICP. Autoregulation of the cerebral vasculature provides the initial protection to maintain cerebral perfusion. However, as the ICP increases, autoregulation may be lost and cerebral blood flow decreased. This results in the potential for significant secondary neuronal injury. CPP may be reduced by raised ICP, hypotension, or both. Additional manifestations of increased ICP include papilledema, Cushing triad (bradycardia, hypertension, irregular respirations), bulging fontanel, and signs of third nerve (ptosis, anisocoria) or sixth nerve (lateral rectus weakness) compression. The presence of intracranial hypertension may mimic global encephalopathy with increasing confusion and combativeness progressing to coma and brain- stem compression. These are late signs of increased ICP and indicate that herniation of brain structures is occurring; this is life threatening and requires immediate intervention.

Herniation.

Coma may precede herniation of intracranial contents. Brainstem herniation proceeds from higher to lower brain centers. Coma is followed by decorticate rigidity, small pupils, and Cheyne-Stokes breathing. As the midbrain and pons become involved, posturing changes to decerebrate, pupils become mid-position and nonreactive, and the breathing pattern is hyperpneic. As the medulla is

compromised, the blood pressure and heart rate fluctuate greatly, the patient becomes flaccid, and breathing is irregular and then absent. Unilateral uncal lobe herniation may be heralded by ipsilateral anisocoria, loss of pupillary reflexes, and ptosis caused by compression of the third cranial nerve.

Infratentorial Lesions.

Lesions in the infratentorial region can cause coma, cranial nerve palsies, and respiratory abnormalities at an earlier stage in the disease. Obstructive hydrocephalus may result from the compression of the circulatory or cerebrospinal fluid pathways. Such compression is seen with posterior fossa tumors. These may produce brainstem compression without the depth or severity of encephalopathy in more global cortical diseases. The hallmark of infratentorial herniation is early respiratory and autonomic impairment, whereas the pupillary responses may be preserved. Neck pain may be present as well as vocal cord paralysis.

Principles of Support for Global Neurologic Dysfunction

NORMALIZE THE CIRCULATION AND RESPIRATION.

The basics of neurologic stabilization include the ABCs of resuscitation (see Chapter 57.1) and maintenance of adequate oxygenation and perfusion. The decision to intubate the trachea and institute mechanical ventilation is determined by the need to control the airway; are protective airway reflexes (i.e., cough and gag) intact to protect the child from aspiration? In some stuporous cases, the patient's respiratory drive may be intact but the gag reflex may be absent or upper airway muscle tone lax. In the case of Guillain-Barré syndrome, one should not wait for respirations to be shallow; the gag reflex may be absent. If the patient can protect the airway, the work of breathing must be maintained to ensure adequate gas exchange and avoid

hypercarbia and hypoxemia. In addition, intubation may be needed to gently hyperventilate the patient to produce mild hypocarbia, thus acutely reducing ICP. The mechanism selected to secure the airway includes the availability of appropriate equipment, medication, and personnel to facilitate the intubation in as rapid and atraumatic manner as possible. The medications and methods used for intubation should not further raise ICP. A form of rapid sequence intubation is used with appropriate positioning and support for the neck (see Chapter 57.1). Once the airway is secured and the patient's oxygenation and ventilation have been stabilized, the clinician can focus on the circulation system.

Circulation should be normalized, with the aim of optimizing perfusion to all tissues. If after appropriate fluid resuscitation the patient still has poor perfusion, one should consider the use of inotropic agents to enhance cardiac output. One must carefully determine if there are ongoing blood or fluid losses that need to be addressed to facilitate fluid resuscitation. Once the patient's cardiac output has been stabilized, modest fluid restriction is beneficial, mainly to avoid fluid overload and attendant hypervolemia. One should not restrict fluids to the point of oliguria. Little benefit has been demonstrated with fluid restriction. The urine output and serum sodium need to be monitored and the fluid restriction considered if hyponatremia from the syndrome of inappropriate antidiuretic hormone secretion (SIADH) begins to develop.

FLUID MANAGEMENT IN THE PRESENCE OF SIADH OR DIABETES INSIPIDUS (DI).

Inappropriate secretion of antidiuretic hormone is a frequent accompaniment of CNS injury or infection and can occur with many types of brain injury as well as with pulmonary disease. The diagnosis of SIADH is suggested by analyzing urine (higher than expected) and serum (low) osmolalities in the hyponatremic patient. Urine osmolality is often higher than the serum osmolality. The effects of SIADH can be lessened by fluid restriction; SIADH is usually self-limited, although it may persist during mechanical ventilation. Patients with SIADH are normotensive and not edematous in contrast to patients with hyponatremia and heart or hepatic failure (dilutional hyponatremia) or adrenal or renal insufficiency (salt-losing states).

Diabetes insipidus heralds a very poor outcome in the child with significant brain injury. A damaged pituitary or hypothalamus can induce massive unregulated urine output, dehydration, and a rapidly rising serum sodium concentration. The sodium level can rise as much as 30?mEq/L in a few hours. Diabetes insipidus can be managed with vigorous intravenous fluid intake, but it is better controlled with vasopressin or desmopressin.

REDUCTION OF INTRACRANIAL HYPERTENSION.

The goal of therapy is to maintain CPP greater than 40?mm?Hg in infants and toddlers, greater than 50?mm?Hg in young children, and greater than 60–70?mm?Hg in adolescents.

Intubation, Ventilation, and Positioning. The initial and most rapid therapeutic intervention for reducing intracranial hypertension requires endotracheal intubation and monitoring of the blood gases to ensure appropriate oxygenation and ventilation to keep the Pa_{CO_2} at 30–35?mm?Hg. Mild hyperventilation is helpful because it reduces cerebral blood flow through vasoconstriction of the cerebral blood vessels. Significant hyperventilation ($Pa_{CO_2} < 25$?mm?Hg) may possibly cause cerebral ischemia. Proper positioning places the patient's head in the midline and elevated about 30 degrees, to allow optimal venous drainage. Patient movement should be minimized with strong sedation and, if necessary, muscle relaxants (e.g., intermittent or continuous infusions of benzodiazepines, narcotics, and vecuronium).

Ventricular Drainage, Diuretics, Steroids, and Other Therapies. Reduction in cerebrospinal fluid volume may be helpful in managing increased ICP. If a ventriculostomy has been placed, periodic fluid removal will reduce ICP and improve CPP. Further reduction in circulating blood volume occurs with the use of diuretics. Commonly, diuretic therapy in the form of mannitol or furosemide has been used acutely. Mannitol is commonly useful in the acute treatment of intracranial hypertension. It is an osmotic diuretic and promotes a shift of fluid from the intracellular to the intravascular space. A dose ranging from 0.25–0.5?g/kg is effective. Mannitol is less beneficial with severe disruption of blood-brain barrier because it may enter the CNS and draw fluid into the brain. If mannitol creates a very hyperosmolar circulatory state, renal failure and hemolysis may ensue. Furosemide is a safer but less effective alternative. Usually the combination of both

agents is prescribed. Hypertonic saline infusions may also be beneficial. Intravenous corticosteroids are not indicated if there is diffuse cerebral injury, but they have benefit in the localized edema surrounding an intracranial mass (abscess or tumor). Surgical decompression of blood is essential. The use of barbiturate coma with electroencephalographic monitoring has been used with varying success to reduce cerebral metabolic demands and ICP. Unfortunately, barbiturate coma may reduce cardiac output and produce hypotension.

SEIZURES

Benzodiazepines vs. Antiepileptics.

Both benzodiazepines and other anticonvulsant drugs reduce cerebral metabolism; the anticonvulsant agents are more effective at suppressing subsequent seizure activity. Seizures lasting longer than 10?min must be treated aggressively. Seizures lasting longer than 30?min are status epilepticus; refractory status epilepticus occurs when despite anticonvulsant therapy, seizures last greater than 60?min. Benzodiazepines (lorazepam or diazepam) are very effective first-line agents for treating seizures in patients with hypoxic-ischemic encephalopathy and other causes of status epilepticus. Both have rapid (3–5?min) onset of action. Because diazepam has a short half-life, it must be followed with another longer-acting agent (phenytoin or phenobarbital). The half-life of phenobarbital is quite long, it has sensitive properties, and at high doses an adequate assessment by the neurologic examination will not be possible. Phenytoin should not cause sedation and should not change the results of neurologic examination; its use is limited by its potential cardiovascular and CNS toxicity (in high doses). The two drugs are often used in combination in refractory status. Fosphenytoin is often used instead of phenytoin. Fosphenytoin and phenobarbital are also used as first-line agents in status epilepticus. Additional agents used in status epilepticus include midazolam and the intravenous form of valproic acid. If seizures are refractory, repeated doses of phenobarbital should be given to achieve high levels (50–100?mg/dL). In addition a continuous intravenous infusion of midazolam may be used. Propofol has also been used with some success in treating refractory seizures.

Barbiturate-Induced Coma.

If seizures are refractory to phenobarbital and fosphenytoin, a barbiturate-induced coma may be necessary, using a shorter-acting agent (usually pentobarbital). Therapy may be titrated to a burst suppression pattern of the electroencephalogram; this may not be necessary if seizures cease before this. Monitoring is best conducted with a continuous electroencephalogram. Continuous infusions of midazolam are an alternative approach to treat refractory status. Complications of high-dose barbiturate coma include cardiovascular depression with decreased cardiac output that often requires inotropic drug support.

HYPOTHERMIA.

Mild hypothermia (e.g., 32°–34°C) results in a decrease in cerebral metabolism and a reduction of ICP but has the added potential risks of superinfection and dysrhythmias. Hypothermia has not been shown to reliably improve outcome in severe CNS illness. Moderate hypothermia may be beneficial in patients with a GCS score of 5–7 when used for 24?hr. Patients with a GCS score less than 4 may not benefit from hypothermia treatment. Patients with nonpenetrating trauma,

age younger than 30 yr, and CPP more than 50?mm?Hg and who were hypothermic (<35°C) on admission tend to have a better response to induced hypothermia.

57.8 Acute Care of the Multiple Trauma Victim

Peter S. Dayan
Bruce L. Klein

Epidemiology.

Injury is the leading cause of death for children aged 1–14 yr in industrialized nations (see Chapter 50). Deaths represent only a small fraction of the total trauma burden. For every child who dies in the Netherlands from home or leisure unintentional injury, there are another 160 hospital admissions and 2,000 emergency department (ED) visits. Many survivors have temporary or permanent functional limitations.

Trauma is classified by the number of significantly injured body parts (one or more), the severity of injury (mild, moderate, or severe), and the mechanism of injury (blunt or penetrating). In childhood blunt trauma predominates, accounting for over 90% of admissions. In adolescence, penetrating trauma increases in frequency and has a higher mortality. This chapter focuses on the emergency management of the child with moderate to severe injury due to blunt trauma.

Regionalization and Trauma Teams.

Decreased mortality and morbidity has been noted in geographic regions with comprehensive, coordinated trauma systems. Designated trauma centers, in particular, save lives. At the scene, paramedics should administer necessary advanced life support and do triage (Box 57–6). Generally, it is preferable to bypass local hospitals and rapidly transport a seriously injured child directly to a pediatric trauma center (or trauma center with pediatric commitment).

When the receiving ED is notified before the child's arrival, the trauma team must be mobilized. Each member has defined tasks. A senior surgeon or an emergency physician leads the team. Team compositions vary somewhat from hospital to hospital; the model used at Children's National Medical Center (Washington, DC) is depicted in Figure 57–25 . Consultants, especially neurosurgeons and orthopedic surgeons, must be immediately available, and the operating room (OR) staff should be alerted.

Physiologic status, anatomic locations, and/or mechanism of injury are used to determine whether to activate the trauma team. More importance should be placed on physiologic compromise and less on mechanism of injury. Scoring scales using similar parameters have been developed to predict patient outcome (see Chapter 50) (Tables 57–18 and 57–19).

Box 57.8-6. Children Requiring Pediatric Trauma Center Care

Patients with serious injury to more than one organ or system

Patients with one-system injury who require critical care or monitoring in an intensive care unit

Patients with signs of shock who require more than one transfusion

Patients with fracture complicated by suspected neurovascular or compartment injury

Patients with fracture of axial skeleton

Patients with two or more long-bone fractures

Patients with potential replantation of an extremity

Patients with suspected or actual spinal cord or column injuries

Patients with head injury with any one of the following:

- Orbital or facial bone fracture
- Cerebrospinal fluid leaks
- Altered state of consciousness
- Changing neural signs
- Open-head injuries
- Depressed skull fracture
- Requiring intracranial pressure monitoring

Patients suspected of requiring ventilator support

Requiring intracranial pressure monitoring

Patients suspected of requiring ventilator support

Primary Survey.

The American College of Surgeons advocates use of a primary and secondary survey to evaluate trauma victims in the ED. During the primary survey, the physician quickly assesses and treats any life-threatening injuries. The principal causes of death shortly after trauma are airway obstruction, respiratory insufficiency, circulatory collapse from hemorrhage, and central nervous system injury. Therefore, the primary survey addresses the *ABCDE*s: A, Airway; B, Breathing; C, Circulation; D, neurologic Deficit; and E, Exposure of the patient and control of the Environment.

AIRWAY/CERVICAL SPINE.

Optimizing oxygenation and ventilation, while protecting the cervical spine from potential further injury, is of paramount importance. Initially, any child sustaining multiple, blunt trauma must be suspected of having a cervical spine injury. Children are at increased risk for such injuries owing to their relatively large heads, which augment flexion-extension forces, and weak neck muscles, which predispose to ligament injuries. Unnecessary movement of the cervical spine can lead to paralysis. The cervical spine should be immobilized in neutral position using a stiff collar, head blocks, and tape or cloth placed across the forehead, torso, and thighs to restrain the child to a rigid backboard.

Airway obstruction presents as snoring, gurgling, hoarseness, stridor, and/or diminished breath sounds despite good respiratory effort. Children are more likely than adults to develop airway obstruction because of their smaller oral cavities, proportionately larger tongues and greater amounts of tonsillar and adenoidal tissue, higher and more anterior glottic openings, and narrower tracheas. Obstruction is common in patients with severe head injuries for several reasons, including decreased muscle tone that allows the tongue to fall posteriorly, occluding the airway. With trauma, obstruction also can result from fractures of the mandible or facial bones, crush injuries of the larynx or trachea, secretions such as blood or vomitus, or foreign body aspiration.

If it is necessary to open the airway, a jaw thrust *without head tilt* is recommended (see Chapter 57.1). This procedure minimizes cervical spine motion. In an unconscious child, an oropharyngeal airway then can be inserted to prevent posterior displacement of the mandibular tissues. A semiconscious child will gag with an oropharyngeal airway but may tolerate a nasopharyngeal airway. If these maneuvers plus suctioning do not clear the airway, oral endotracheal intubation is indicated.

Emergent cricothyrotomy is rarely required.

Figure 57.8-25 Trauma team inner core members at Children's National Medical Center (Washington, DC). Outer core members include a nursing administrator, social worker, radiology technician, transplant technician, and security officer.

TABLE 57.8-18 -- Pediatric Trauma Score

Clinical Category	Score		
	+2	*+1*	*-1*
Size	=20?kg	10–20?kg	<10?kg
Airway	Normal	Maintainable	Unmaintainable
Systolic blood pressure*	=90?mm?Hg	50–90?mm?Hg	<50?mm?Hg
Central nervous System	Awake	Obtunded/loss of consciousness	Coma/decerebrate
Open wound	None	Minor	Major/penetrating
Skeletal	None	Closed fracture	Open/multiple fractures

From Ford EG:Trauma triage. In Ford EG, Andrassy RJ (editors): Pediatric Trauma Initial Assessment and Management. Philadelphia, WB Saunders, 1994, p 112.

* *Use this if blood pressure cuff not available: +2 = palpable pulse at wrist; +1 = no palpable pulse in groin; -1 = no palpable pulse. If total score <8, refer to pediatric trauma center.*

BREATHING.

Breathing is assessed by counting the respiratory rate; visualizing chest wall motion for symmetry, depth, and accessory muscle use; and auscultating breath sounds in both axillae. In addition to looking for cyanosis, pulse oximetry is standard. If breathing is inadequate, bag-valve-mask ventilation with 100% oxygen must be initiated immediately, followed by endotracheal intubation. End-expiratory CO_2 detectors help verify accurate tube placement.

TABLE 57.8-19 -- Revised Trauma Score*

Revised Trauma Score	Glasgow Coma Scale Score	Systolic Blood Pressure (mm Hg)	Respiratory Rate (breaths/min)
4	13–15	>89	10–20
3	9–12	76–89	>29
2	6–8	50–75	6–9
1	4–5	1–49	1–5
0	3	0	0

From Fitzmaurice LS: Approach to multiple trauma. In Barkin RM (editor): Pediatric Emergency Medicine, 2nd ed. St. Louis, CV Mosby, 1997, p 224.

** A score of 0–4 is given for each variable, then added (range, 1–12). A score =11 indicates potentially important trauma.*

Head trauma is the most common cause of respiratory insufficiency. An unconscious child with a severe head injury may develop a variety of breathing abnormalities, including Cheyne-Stokes respirations, slow irregular breaths, or apnea.

Although less common than a pulmonary contusion, tension pneumothorax and massive hemothorax is immediately life threatening (Box 57–7). Tension pneumothorax occurs when air accumulates under pressure in the pleural space. The adjacent lung is compacted, the mediastinum is pushed toward the opposite hemithorax, and the heart, great vessels, and

Box 57.8-7. Life-Threatening Chest Injuries

TENSION PNEUMOTHORAX

One-way valve leak from lung parenchyma

Complete collapse with mediastinal and tracheal shift to side opposite the leak

Compromises venous return and decreases ventilation of other lung

Clinically, manifests as respiratory distress, unilateral absent breath sounds, tracheal deviation, distended neck veins, tympany to percussion of involved side, and cyanosis

Relieve first with needle aspiration, then with chest tube drainage

OPEN PNEUMOTHORAX (SUCKING CHEST WOUND)

Effect on ventilation depends on size

MAJOR FLAIL CHEST

Usually caused by blunt injury resulting in multiple rib fractures

Loss of bone stability of thoracic cage

Major disruption of synchronous chest wall motion

Mechanical ventilation and positive end-expiratory pressure required

MASSIVE HEMOTHORAX

Must be drained with large-bore tube

end-expiratory pressure required

MASSIVE HEMOTHORAX

Must be drained with large-bore tube

Initiate drainage only with concurrent vascular volume replacement

CARDIAC TAMPONADE

Beck triad:

1. Decreased or muffled heart sounds
2. Distended neck veins from increased venous pressure
3. Hypotension with pulsus paradoxus (decreased pulse pressure during inspiration)

Must be drained

From Krug SE: The acutely ill or injured child. In Behrman RE, Kliegman RM (editors): Nelson Essentials of Pediatrics , 4th ed. Philadelphia, WB Saunders, 2002, p 97.

contralateral lung are compressed. Both ventilation and cardiac output are impaired. Typical findings include cyanosis, tachypnea, retractions, asymmetric chest rise, contralateral tracheal deviation, diminished breath sounds on the ipsilateral side, subcutaneous emphysema, and signs of shock. Needle thoracentesis, followed by thoracostomy tube insertion, is diagnostic and lifesaving.

Hemothorax results from injury to the intercostal vessels, lungs, heart, or great vessels. When ventilation is adequate, fluid resuscitation should begin before evacuation, because a large amount of blood may drain through the chest tube, resulting in shock.

CIRCULATION.

The most common type of shock in trauma is hypovolemic shock due to hemorrhage (see Chapter 57.2). Signs of shock include tachycardia, weak peripheral pulses, delayed capillary refill, cool mottled skin, and altered mental status. Early in shock, blood pressure remains normal, because of compensatory increases in heart rate and peripheral vascular resistance. An individual can lose up to 25% of blood volume before the blood pressure declines. It is important to note that 25% of blood volume equals 20?mL/kg, which is only 200?mL in a 10-kg child. With losses greater than 25%, hypotension ensues. Losses greater than 50% cause severe hypotension that, if prolonged, may become irreversible.

Direct pressure should be applied to control external hemorrhage. Blind clamping of bleeding vessels is not advisable because of the risk of damage to adjacent structures.

Cannulating a larger vein, such as an antecubital vein, is usually the quickest way to achieve intravenous access. A short, large-bore catheter offers less resistance to flow, allowing for more rapid administration. Ideally, a second catheter should be placed within the first few minutes of resuscitation in a severely injured child. If intravenous access proves difficult, an intraosseous catheter can be inserted; all medications and fluids can be administered intraosseously. Central venous access using the Seldinger technique (e.g., via the femoral vein) or surgical cutdown (e.g., over the saphenous vein) are other alternatives in experienced hands.

Aggressive, intravenous fluid resuscitation is essential early in shock to prevent further deterioration (20?mL/kg). Isotonic crystalloid solution, such as lactated Ringer or normal saline (20?mL/kg), should be infused rapidly. Currently, no consensus exists supporting routine use of colloid or hypertonic saline solution. When necessary, repeated crystalloid boluses can be given. Many children stabilize with crystalloid solution alone. However, if the patient is still in shock after repeated boluses, 10–15?mL/kg of cross-matched, packed red blood cells should be transfused. Although less desirable, type-specific or O-negative cells can be substituted pending availability of cross-matched blood. When shock persists despite these measures, surgery to stop internal hemorrhage is usually indicated.

NEUROLOGIC DEFICIT.

In the primary survey, neurologic status is briefly assessed by evaluating the level of consciousness and determining pupil size and reactivity. Level of consciousness can be classified using the mnemonic *AVPU: A*lert, responsive to *V*erbal commands, responsive to *P*ainful stimuli, or *U*nresponsive.

Head injuries account for approximately 70% of pediatric blunt trauma deaths. Primary direct cerebral injury occurs within seconds of the event and is irreversible. Secondary injury is caused by subsequent anoxia or ischemia. Therefore, the goal is to minimize secondary injury by ensuring adequate oxygenation, ventilation, and perfusion and maintaining normal intracranial pressure (ICP). A child with severe neurologic impairment, such as a Glasgow Coma Scale (GCS) (see Table 57–3) score of 8 or less, should be intubated (see Chapter 57.7).

Signs of increased ICP, including progressive neurologic deterioration or evidence of transtentorial herniation, must be treated immediately. Hyperventilation lowers Pa_{CO_2} , resulting in cerebral vasoconstriction, reduced cerebral blood flow, and decreased ICP. Vigorous, *prolonged* hyperventilation is no longer recommended, because the consequent vasoconstriction may excessively decrease cerebral perfusion. Brief hyperventilation is an option for patients with acute increases in ICP. Mannitol lowers ICP and may improve survival. Because mannitol acts via osmotic diuresis, it can exacerbate hypovolemia and must be used cautiously. Neurosurgical consultation is

mandatory. If signs of increased ICP persist, the neurosurgeon must decide whether to obtain a CT scan and/or operate.

EXPOSURE/ENVIRONMENTAL CONTROL.

All clothing should be cut away to reveal any injuries. Cutting is quickest and also minimizes unnecessary patient movement.

Children often arrive mildly hypothermic owing to their higher body surface area to mass ratios. They can be warmed using radiant heat as well as heated blankets and intravenous fluids.

Secondary Survey.

During the secondary survey, the physician completes a detailed, head-to-toe, physical examination.

HEAD TRAUMA.

A GCS or Pediatric GCS score (see Table 57–3) should be assigned to every child with significant head trauma (see Chapter 57.7). This scale assesses eye opening and motor and verbal responses. In the Pediatric GCS, the verbal score is modified for age. The GCS further categorizes neurologic disability, and serial measurements identify improvement or deterioration over time. Patients with low scores 6–24?hr after injury have poorer prognoses.

Head CT scan without contrast medium enhancement has become standard to determine the type of injury. In severely injured children, diffuse cerebral injury with edema is a serious and common finding on CT scan. Focal evacuable hemorrhagic lesions (e.g., epidural hematoma) occur less commonly but may require immediate neurosurgical intervention.

ICP monitoring is used routinely for children with severe brain injuries (e.g., GCS score of 8 or less with an abnormal CT). Although its benefit in improving outcome is uncertain, it has gained wide neurosurgical support. An advantage of an intraventricular catheter, in contrast to an intraparenchymal device, is that cerebrospinal fluid can be drained to treat acute rises in ICP.

A child with a severe brain injury must be treated aggressively in the ED because it can be difficult early in the course to accurately predict long-term neurologic outcome. Compared with adults with similar injuries, children have improved functional outcomes perhaps in part because of the elastic nature of their maturing brains. Nonetheless, diffuse cerebral edema after head trauma has a poor prognosis.

CERVICAL SPINE TRAUMA.

Cervical spine injuries occur in less than 2% of children with multisystem trauma but are associated with significant mortality and morbidity. Bony injuries occur mainly from C1-C4 in children younger than 8 yr of age. In older children, they occur equally in the upper and lower cervical spine. The mortality rate, however, is significantly higher in patients with upper cervical spine injuries. *SCIWORA* (cervical spinal cord injury without radiographic [bone] abnormalities on plain films) occurs in approximately 20% of children with cervical spine injuries. Approximately one third of all patients with cervical spine injuries have neurologic deficits.

Evaluation begins with a detailed history and neurologic examination. Identifying the mechanism of injury helps one estimate the likelihood of a cervical spine injury. Both the patient and paramedic should be asked whether there were any neurologic symptoms or signs, such as weakness or abnormal sensation, which resolved before arrival. In a child with transient neurologic complaints and normal x-ray films, SCIWORA still must be considered.

Whenever the history, physical examination, or mechanism of injury suggests a cervical spine injury, radiographs (including lateral, anteroposterior [AP], and odontoid views)

---

should be obtained after initial resuscitation. Cervical spine CT scan can be a valuable adjunct to plain films; some centers use CT as the primary diagnostic tool. Magnetic resonance imaging is especially useful for a child with suspected SCIWORA.

Rapid diagnosis of spinal cord injury is essential. Initiating high-dose intravenous methylprednisolone within 8?hr of spinal cord injury improves motor outcome at 1 year and is standard therapy.

THORACIC TRAUMA.

Pulmonary contusions occur frequently in younger children with blunt chest trauma. A child's chest wall is relatively pliable; therefore, less force is absorbed by the rib cage and more is transmitted to the lungs. Respiratory distress may be noted in the ED or develop during the first 24?hr of hospitalization.

Rib fractures result from significant external force and are noted in patients with more severe injuries and are associated with a higher mortality rate. Flail chest, which is caused by multiple rib fractures, is rare in children. The differential diagnosis of life-threatening cardiopulmonary injuries following thoracic trauma is noted in Table 57–20 .

ABDOMINAL TRAUMA.

Liver and spleen contusions, hematomas, and lacerations account for the majority of intra-abdominal injuries due to blunt trauma. The kidney, pancreas, and duodenum are relatively spared, owing to their retroperitoneal location. Pancreatic and duodenal injuries are more common after a bicycle handlebar impact or a direct blow to the abdomen.

Although a thorough examination for intra-abdominal injuries is essential, this often proves difficult. Misleading findings can result from gastric distention from crying or because a toddler will not cooperate. Calm reassurance and gentle palpation before painful procedures helps with the examination. Important aspects of the examination include looking for distention and bruises, palpating for tenderness, and performing a rectal examination to assess for blood. Specific signs give insight into the mechanism of injury and potential for particular injuries. For example, a lap belt mark across the abdomen suggests the possibility of a bowel or mesentery injury. Pain in the left shoulder may signify splenic trauma.

An abdominal CT scan with intravenous contrast medium enhancement rapidly identifies structural and functional abnormalities and is the preferred study in a stable child. It has excellent sensitivity and specificity for splenic, hepatic, and renal injuries but is less sensitive for intestinal and pancreatic injuries. Administering oral contrast adds little for most injuries. The use of oral contrast in children with possible bowel perforation is controversial, because false-negative scans are common. Ultrasonography may be used to follow injuries.

Nonoperative treatment has become standard for hemodynamically stable children with splenic, hepatic, and renal injuries from blunt trauma. The majority of such children can be treated nonsurgically. In addition to avoiding perioperative complications,

TABLE 57.8-20 -- **Differential Diagnosis of Immediately Life-Threatening Cardiopulmonary Injuries**

	Tension Pneumothorax	**Massive Hemothorax**	**CardiacTamponade**
Breath Sounds	Ipsilaterally decreased	Ipsilaterally decreased	Normal
Percussion Note	Hyperresonant	Dull	Normal

nonoperative treatment also appears to decrease the need for blood transfusions as well as shorten hospital stay. Indications for laparotomy include persistent hemodynamic instability, the need for repeated transfusions (~40?mL/kg/24?hr), and bowel perforation. Splenic repair if possible is preferable to splenectomy in cases of severe splenic injury.

LOWER GENITOURINARY TRAUMA.

The perineum should be inspected, pelvic stability assessed, and a rectal examination performed to evaluate for lower genitourinary trauma. Urethral injuries are more common in males. Findings suggestive of a urethral injury include scrotal or labial ecchymoses, blood at the urethral meatus, gross hematuria, and a superiorly positioned prostate (in an adolescent male). Any of these findings represents a contraindication to urethral catheter insertion and warrants consultation with a urologist. A pelvic fracture is also a marker for potential genitourinary injury. Retrograde urethrocystogram and CT scan of the pelvis and abdomen are used to determine the extent of injury.

EXTREMITY TRAUMA.

Thorough examination of the extremities is essential because fractures are among the most frequently missed injuries in children with multiple trauma. All limbs should be inspected for deformity, swelling, and bruises; palpated for tenderness; and assessed for active and passive range of motion, sensory function, and perfusion.

Before obtaining x-ray films, suspected fractures and dislocations should be immobilized and an analgesic administered. Splinting a femur fracture helps alleviate pain and may decrease blood loss. An orthopedic surgeon must be consulted immediately to evaluate a child with a compartment syndrome, other causes of neurovascular compromise, or open fracture (Chapter 673).

Radiologic and Laboratory Evaluation.

To avoid misdiagnoses, some authorities recommend routinely obtaining a large array of studies in the ED. These include lateral cervical spine, AP chest, and AP pelvis x-ray films; arterial blood gas analysis; complete blood cell count; electrolytes; blood glucose; blood urea nitrogen; creatinine; amylase; liver function tests; prothrombin and partial thromboplastin times; type and cross match; and urinalysis. One benefit of standardizing the evaluation of the major trauma victim is that fewer decisions need to be made on an individual basis, which sometimes expedites ED management.

Research has highlighted some of the advantages and limitations of these studies. The lateral cervical spine x-ray film can miss significant injuries. When it is necessary to assess oxygenation, ventilation, and acid-base status, an arterial blood gas is useful. A large base deficit is associated with a higher mortality rate. Hemoglobin and hematocrit levels provide baseline values in the ED but may not have equilibrated after a hemorrhage at the time of measurement. Abnormal liver function tests or serum amylase levels may be noted in patients with significant abdominal trauma, but most patients with significant blunt trauma to the abdomen have clinical indications for CT scanning or surgery. The vast majority of previously healthy children have normal coagulation profiles; however, these may become abnormal after major head trauma. Although routine urinalysis or dipstick testing for blood has been recommended for children, data from large adult studies suggest this may be unnecessary in patients without gross hematuria or hypotension.

Cardiopulmonary Arrest.

Preventing physiologic deterioration is crucial. Children who sustain multiple injuries from blunt trauma have a 0–2% survival rate once pulseless cardiac arrest occurs. Unfortunately, those few who survive resuscitation after pulseless arrest are likely to have severe neurologic impairment.

Psychological and Social Support.

Serious multisystem trauma may result in significant long-term psychological and social difficulties for the child and family, particularly when there is a major head injury. Children are at risk of depressive symptoms

and post-traumatic stress disorder. Caregivers face persistent stress and have been noted to have more psychological symptoms. Psychological and social support, therefore, is extremely important. **REFERENCES**

Chapter 58 - Acute (Adult) Respiratory Distress Syndrome (ARDS)

Lorry R. Frankel
Joseph V. DiCarlo

Acute respiratory distress syndrome (ARDS) is diagnosed in 2.5–3% of children in the pediatric intensive care unit (PICU); these children account for about 8% of total patient-days and 33% of the deaths. ARDS is more likely to occur in children already compromised by serious illness.

ARDS is an acute process. It may begin with an acute lung injury that progresses rapidly to respiratory failure (Box 58–1). The diagnosis is often delayed in children because pulmonary artery catheters are rarely used in pediatrics and because cardiac function is often abnormal because of hypoxia, shock, or sepsis. The diagnosis can be hastened by a high index of suspicion and an echocardiogram.

Epidemiology and Etiology.

Risk factors for ARDS include sepsis, shock, trauma, multiple transfusions, pneumonia, acute chest syndrome (sickle cell anemia), aspiration of gastric contents, pulmonary contusion, fat emboli, near-drowning, inhalation injury, drug overdose, acute pancreatitis, and reperfusion injury after lung transplantation.

Infectious pneumonia and sepsis are the most frequent causes of ARDS. ARDS is associated with viral pneumonia, particularly respiratory syncytial virus, adenovirus, post-measles pneumonia, and, in immunocompromised children, infection with cytomegalovirus or *pneumocystis carinii*.

The mortality of ARDS is 30–40%; risk factors for death include sepsis, shock, multiple organ dysfunction, increased pulmonary dead space, and failure to improve during the first

Box 58-1. Criteria for Acute Respiratory Syndromes[*]

Acute onset

Bilateral pulmonary infiltrates on radiography[†]

Absence of left-sided heart failure or elevated left atrial pressure or pulmonary artery wedge pressure = 18?mm?Hg[‡]

Acute lung injury: PaO_2 :FIO_2 = 300

Acute repiratory distress syndrome: PaO_2 :FIO_2 = 200

**Criteria are cause independent.*
†Radiographic features are not specific for ARDS.
‡Nonhydrostatic pulmonary edema from pulmonary capillary endothelial cell injury.

week of illness. The mortality rate varies from 24% after severe trauma to 88% after bone marrow transplantation. Severe respiratory failure in bone marrow transplant recipients is not always ARDS; diffuse alveolar damage, the histologic hallmark of the ARDS, is present in only 33% of these children.

Pathogenesis.

ARDS is a pulmonary manifestation of a systemic inflammatory process triggered by various events. ARDS may progress through 2 or 3 phases. In the *acute exudative phase* there is profound and often refractory hypoxia. The chest x-ray film demonstrates pulmonary edema, whereas CT scans show alveolar fluid, atelectasis, and consolidation in the dependent lung zones (less severe but more generalized findings are noted in the nondependent zones). Inflammation with infiltration by neutrophils and macrophages is caused by an excessive presence of proinflammatory cytokines and an imbalance of the anti-inflammatory cytokines. Diffuse alveolar epithelial damage produces protein-rich edema fluid, hyaline membranes, and inactivation of surfactant. Ventilator management strategies, which result in cyclic recruitment (opening) and de-recruitment (closing) of atelectatic alveolar or which cause alveolar overdistention, cause further cytokine release and exacerbate the original diffuse alveolar injury.

The patient may recover or after 1–2 wk may enter the *fibrosing alveolitis phase*, which manifests as continued hypoxia, increased alveolar dead space, further reductions in compliance, pneumothoraces, and pulmonary hypertension, leading to right ventricular failure (cor pulmonale). Patients who die do so in the exudative or fibrosing phase.

Resolution may take 6–12 mo. Residual effects include airway obstruction, restrictive lung disease, poor carbon monoxide diffusion, and exercise intolerance.

Clinical Manifestations.

Acute pulmonary deterioration may not be initially appreciated. During this latent period, patients may exhibit mild respiratory distress with tachypnea, dyspnea, and an increased oxygen requirement. Auscultation of the lungs may reveal clear breath sounds or scattered crackles. Within the next few hours, patients begin to develop more severe hypoxia accompanied by carbon dioxide retention. The onset of ARDS may be quite variable, as seen in patients with infection; very sudden, as with pulmonary gastric fluid aspiration; or insidious, as seen in acute neurologic injury.

Laboratory Findings.

Patients are initially monitored with a pulse oximeter. As the oxygen requirements exceed an F_{IO_2} greater than 0.5% when attempting to maintain the Sa_{O_2} greater than 92%, one must consider the diagnosis of ARDS. An arterial blood gas analysis confirms the increased A-a gradient, and a Pa_{O_2} /F_{IO_2} less than 200 correlates with an intrapulmonary shunt greater than 20%. Radiographic findings are nonspecific; x-ray films are performed to identify other causes of progressive respiratory failure or to determine the presence of cardiomegaly and cardiogenic causes of the pulmonary edema. Over the next few hours the chest films begin to demonstrate interstitial and alveolar pulmonary edema. The use of positive-pressure ventilation may alter the radiographic features of pulmonary edema; based on the alterations in pulmonary function and gas exchange, ARDS is still the most likely diagnosis for the worsening respiratory status. Evidence of barotrauma/volutrauma with alveolar air leak may be seen on serial chest films. CT scans or echocardiography may be occasionally needed to identify other causes of hypoxia and respiratory distress. Although rarely used in pediatrics, a pulmonary artery catheter is helpful in differentiating cardiogenic pulmonary edema from ARDS (see Chapter 55).

Treatment.

Once the diagnosis has been made, the patient should be cared for in the intensive care unit by physicians who have the skills and knowledge in the treatment of ARDS. Efforts should be made at treating the underlying disease (e.g., sepsis, aspiration, shock),

preventing complications (gastric bleeding), and providing supportive care during this period. Patients with ARDS require invasive monitoring of vital signs and blood gases, as well as the placement of a central venous line used to monitor cardiac filling pressures and to administer fluids. A pulmonary artery catheter may be helpful in titrating various ventilator and pharmacologic therapies.

The mainstay of ventilator therapy is the use of a lung protection strategy that includes positive end-expiratory pressures (PEEP) and a low tidal volume. PEEP improves oxygenation by decreasing intrapulmonary shunting. PEEP is usually titrated in increments of 2–4?cm?H_2O with repeated measurement of blood gases. PEEP is adjusted to enable the F_{IO_2} to be lowered to less than 0.6 and have the PaO_2 in the predetermined range to prevent tissue hypoxia (Pa_{O_2} : 55–80?mm?Hg; oxygen saturations: 88–95%). If the PEEP exceeds 15?cm?H_2O, the patient may experience decreased venous return and reduced cardiac output; additional fluids to improve preload and inotropic agents may be needed to enhance blood pressure and cardiac output.

Permissive hypercapnia (permitting the range of $PaCO_2$ to be 55–70?mm?Hg) is the result of low tidal volume (6–7?mL/kg) ventilation used in children with ARDS. Higher ventilator settings, such as tidal volumes of 10–15?mL/kg or peak inspiratory pressures greater than 30?cm?Hg, may predispose the child to ventilator-associated lung injury, such as barotrauma or volutrauma (air leak syndromes, i.e., pneumothorax, pneumomediastinum, pneumopericardium, pneumoperitoneum, and the production of inflammatory cytokines).

Fluid balance is also monitored to try to reduce edema formation. Once shock is treated and perfusion established, a moderate fluid restriction may be helpful.

Various rescue therapies are available for patients not responding to a lung protector strategy on a conventional ventilator (see Chapter 57.4). The use of high-frequency ventilation benefits children weighing less than 30?kg by reducing air leak and permitting adequate ventilation to occur with a lower mean airway pressure and less shear forces on the already injured lung. Inhaled nitric oxide and other selective or nonselective pulmonary vasodilator agents have not been consistently beneficial in treating severe ARDS. The value of exogenous surfactant in non-neonatal respiratory failure is suggested from case reports and uncontrolled studies; however, controlled trials have not demonstrated a clear benefit. Extracorporeal membrane oxygenation (ECMO) has been used to rescue patients with refractory ARDS. Earlier intervention (< 7 days) with ECMO demonstrates improvement in survival. During the late fibrosing alveolitis phase, there is some evidence that corticosteroids are beneficial in enhancing recovery. In addition, ß-agonists may help clear pulmonary edema fluid.

The physician must also treat the underlying disease, prevent nosocomial infections, provide nutritional support (enteral is preferred to parenteral), maintain an adequate cardiac output, and ensure that the patient remains comfortable. Every effort should be undertaken to elucidate the underlying condition associated with the patient's acute deterioration. All central lines should be placed with respect to the maintenance of sterile technique as well as dressing changes and line care to reduce nosocomial infections. Careful assessments and possibly pharmacologic support of the patient's cardiac output are essential to ensure an adequate cardiac output. Pharmacologic agents, which provide appropriate sedation, analgesia, and amnesia, should be used to facilitate ventilation and reduce the patient's discomfort. Blood transfusions may contribute to endothelial injury and nonhydrostatic pulmonary edema. Although increasing the hemoglobin content potentially increases oxygen delivery at hematocrits greater than 35–40%, there may be an adverse effect on the microcirculation (stasis) and a poor outcome.

Chapter 59 - Continuous Hemofiltration

Joseph V. DiCarlo

Continuous venovenous hemofiltration (CVVH) was designed as a renal replacement therapy for acute renal failure (see Chapters 57.5 and 527). It is often used instead of hemodialysis for patients with blood pressure instability; it is generally more efficient than peritoneal dialysis and can also remove excessive fluid in overhydrated anuric patients. CVVH is particularly useful in children with multiple organ dysfunction or failure, whose treatment often requires very large amounts of intravenous fluids. A double-lumen dialysis catheter is placed in a large vein and connected to a blood pump and air filter. The hemofilters have an additional port located in the ultrafiltrate compartment that allows for the countercurrent circulation of an added dialysate solution. This converts CVVH into a hemodialysis system (CVVHD), which augments the clearance of solutes of low molecular weight. To avoid increasing blood viscosity, filtration rate is kept below 25–30%, or replacement intravenous fluids are infused at the proximal (inflow) side of the filter, diluting the blood presented to the filter. Predilution reduces sludging within the filter and may increase filter life, but the efficiency of ultrafiltration is compromised, because the ultrafiltrate now contains a portion of the replacement fluid. Overall efficiency may be enhanced, however, if the ultrafiltration rate is increased. The replacement solution should contain dextrose, sodium, and potassium in physiologic concentrations and bicarbonate, calcium, magnesium sulfate, chloride, and phosphate.

Production of large volumes of ultrafiltrate (1 to 4?L/hr) may enhance clearance of the chemical mediators of sepsis and inflammation to a degree that attenuates those disease states. Timely use of hemofiltration may delay the progression of hepatic encephalopathy long enough to allow liver transplantation. Hemofiltration is also quite effective when placed in the extracorporeal membrane oxygenation (ECMO) circuit during prolonged bypass in patients with fluid overload and renal dysfunction.

Chapter 60 - Transplantation Issues in the PICU

Lawrence H. Mathers
Lorry R. Frankel

Children in the pediatric intensive care unit (PICU) for pretransplant evaluation or for post-transplant care have unique problems that include sustaining a child with end-organ failure while awaiting a donor; complications after transplant such as sepsis, organ rejection, or multiple organ system dysfunction; and various psychologic, ethical, and social issues. Organ and tissue transplantation is a complex process requiring important decisions involving both the donor and the recipient.

Organ and Tissue Donations.

Donors include (1) those who survive the donation (living donor) and (2) those who donate after death (nonliving donor). Living donors include both those who donate a dispensable tissue, such as cartilage, skin, or bone marrow, as well as those who donate a part or all of one of their own vital organs (kidney, partial or split liver, or lung). Acquiring tissue from nonliving donors requires that there be a determination of brain death (see Chapter 64) and that the vital organs remain perfused and oxygenated. In the United States, approximately 20% of nonliving donors are children. Overall the potential to donate is much greater than actual donation, whereas the number of patients on waiting lists exceeds by a factor of 10 the number of needed organs that are donated. Because of this a substantial number of children die while on the waiting list.

Certain medical conditions may preclude donation of organs or tissues: severe organ dysfunction, organ injury from trauma, disseminated malignancy, active infection (including HIV), serious vascular disease, diabetes mellitus, and severe hypertension (Table 60–1). To expand the donor pool, some transplant centers accept organs from patients with bacterial sepsis or meningitis who have been treated with antibiotics for 24–48?hr and have

TABLE 60-1 -- **Contraindications to Organ Donation**

Organ	Relatively Absolute Contraindications	Absolutely Relative Contraindications	Comments
General	Infection: HIV (incl. high-risk groups and hemophiliacs); hepatitis B, antigen-positive; untreated infections	Hepatitis C, CMV, CNS infection, treated infection	Preferably test viral load, p24-antigen; seek to match donor and recipient for CMV
	Malignancies: all except some CNS and nonmelanotic skin tumors	Some CNS tumors	
	SLE and other collagen vascular disease, congenital metabolic disorders, hemoglobinopathies	Hypertension under treatment, diabetes mellitus, sustained hypotension, high-dose inotropes or pressors	
Kidney	Renal disease or trauma amyloidosis, dysproteinemias	Established acute renal failure	Elevated creatinine caused by dehydration is not a contraindication
Liver	Liver disease or trauma, peritonitis	Advanced cardiovascular disease, alcoholism, drug overdose, moderately elevated liver tests	Drug overdose is only a relative contraindication even if paracetamol
Pancreas	Diabetes mellitus, acute or chronic pancreatitis	Previous duodenal or pancreatic surgery	
Heart	Heart disease: valvular, ischemic, cardiomyopathy	Severe chest trauma, prolonged cardiac arrest, varying limits of MAP, CVP, PCWP, ejection fraction, ECG abnormalities	
Lung	History of chronic lung disease, tuberculosis significant acute lung disease, aspiration severe chest trauma or previous surgery	Smoking >20 pack-years, minor opacities on radiography, PaO_2 <300 mm Hg at FIO_2 = 1 and PEEP = 5 mm Hg, positive sputum culture (even yeasts), purulent secretions	Judge both lungs as two separate organs

SLE = systemic lupus erythematosus; CMV = cytomegalovirus; MAP = mean arterial pressure; CVP = central venous pressure; PCWP = pulmonary capillary wedge pressure; PEEP = positive end-expiratory pressure.

From: Lutz-Dettinger N, de Jaeger A, Kerremans I: Care of the potential pediatric organ donor. Pediatr Clin North Am 2001;48:715–49.

had negative repeat cultures. For some transplants, the size and age of the donor and recipient should be similar.

A potential *recipient* of a transplant is usually identified in advance of the actual transplant, but with potential *donors* there is often little time to discuss the subject of organ donation with the family and secure their support for organ donation. A potential recipient of an organ transplant may be in the same hospital as a potential donor, or they may be separated by many hundreds of miles. The distance over which organs for transplantation can be acquired is limited largely by the readiness of the system to respond to a request and the speed of available transport aircraft. A family whose child or other family member is being considered as a potential donor must comprehend all of the factual information about organ donation and must come to terms with the notion of their loved one being a nonliving donor. The team providing care to the potential donor should introduce the concept of organ donation, beginning with a frank assessment of the degree of injury suffered by the potential donor and the futility of any future care. Accepting the futility of future care and considering the possibility of organ donation, often over a matter of just a few hours, is a difficult emotional hurdle for most families; special sensitivity and compassion on the part of the medical team is mandatory. In many states, the law requires that the local transplant coordination program be contacted when the death of any patient is likely.

Evaluation of potential compatibility between donor and recipient is discussed in Chapter 126 and in chapters addressing specific organ and tissue transplants. *Hyperacute rejection* may occur within minutes of the solid organ transplant in the operating room or in the PICU. It results from the presence of preformed antibodies; blood flow to the transplant is usually compromised by the acute reaction. The organ must be removed immediately or rested as the body is supported (e.g., dialysis, extracorporeal membrane oxygenation [ECMO] in postcardiac transplant recipients). Immune responses, immunosuppression, and *acute* and *chronic rejection* are discussed in Chapters 126 and 128 . Admission to a PICU is not required for bone marrow transplantation unless severe complications develop. Solid organ transplants that include heart, heart/lung, liver, or kidney require major surgery and result in admission to a PICU, often before and after the transplantation (kidney transplants in older

children may be an exception). Many children awaiting solid organ transplantation are in a deteriorating state. Pretransplant treatment of the unstable potential recipient is just as important as postoperative care.

Complications of Bone Marrow Transplantation (BMT).

Ten to 15 per cent of children having BMT require a PICU because of life-threatening complications, especially those that occur in the first 40 days after transplantation. Complications include significant fluid and electrolyte problems, infections, signs of hemodynamic instability, renal failure, airway obstruction, or progressive respiratory failure. Patients requiring mechanical ventilation after BMT have a very high mortality. Early institution of hemofiltrations may improve outcomes.

Acute *graft versus host disease* (GVHD) may present as cholestasis, erythematous maculopapular rash, and diarrhea requiring PICU management (see Chapter 127). Chronic GVHD often follows acute GVHD.

Veno-occlusive disease, a thrombotic disorder producing clots in the small hepatic venules, is the third most frequent complication of BMT and occurs most often in patients undergoing BMT for malignancy. These patients may have severe hepatic dysfunction, resulting in ascites, respiratory distress, and other evidence of organ failure that may require aggressive treatment, including fluid therapy, anticoagulation, and sometimes thrombolytic agents or procedures.

Infections are of major concern because these children are both immunologically suppressed and neutropenic. Patients should be placed in protective isolation to limit infectious exposures. Opportunistic infections are discussed in Chapter 164 . Seizures, encephalopathy, and psychiatric disturbances associated with infections or drug toxicity require aggressive diagnostic and therapeutic interventions.

Thrombocytopenia may result in bleeding from the respiratory and gastrointestinal tract. Efforts are directed at maintaining platelet counts greater than 50,000 when bleeding is present. Children may require nasal packing for severe nosebleeds. Clotting factors may be required if a coagulopathy is present; this is a high risk in children having veno-occlusive disease. Patients also require red blood cell transfusions for a low hematocrit due to bleeding and the inability to produce red blood cells before marrow engraftment.

Oncologists and intensivists need to confer on all BMT recipients in the PICU, to assist the family and the care team in understanding the realistic prospects for success with continued treatment. The PICU staff, in turn, must understand that BMT recipients can become very ill from the immunosuppressive therapy and numerous complications but can still recover. Children with oncologic diseases and their families have typically lived with the disease for months or even years and are prepared for a protracted struggle against complications of their transplants. However, they need to have realistic expectations about the treatment of BMT complications. Frequent care conferences, involving oncologists, intensivists, primary care pediatrician, and family, are often necessary to provide optimal care in these complicated cases.

Heart Transplantation (see Chapter 435.1).

Most potential pediatric heart transplant patients are transferred to a PICU before transplant to receive inotropic agents (dobutamine), chronotropic agents (isoproterenol), and afterload-reducing agents (milrinone, dobutamine) aimed at maximizing cardiac output. After transplant, they are admitted to the PICU for close postoperative management and weaning from pressors, intravascular monitors, and respiratory support. Early post-transplant complications include hyperacute rejection, acute rejection, bradycardia, and dysrhythmias. Later, rejection may still occur, along with various infections, accelerated coronary artery atherosclerotic disease (manifest

by ischemia, dysrhythmias, heart failure), and lymphoproliferative malignancies secondary to immune suppression. If the transplanted heart begins to fail, vasoreactive agents, extracorporeal membrane oxygenation, or ventricular assist devices may be necessary, and, as a last resort, re-transplantation may be required (most centers place patients with failing recently transplanted organs at the top of their transplant lists). Rejection is confirmed by transcatheter myocardial biopsy.

Lung Transplantation (see Chapter 435.2).

Children with cystic fibrosis, primary pulmonary hypertension, and a_1 -antitrypsin deficiency are among the primary candidates for pediatric lung transplantation. Recipients about to undergo lung transplantation may need to be placed on cardiopulmonary bypass if they cannot sustain adequate ventilation and oxygenation on only one lung. Hyperacute and acute rejection may occur with lung transplants as with other organs. More than half of all recipients experience some degree of rejection in the first 3 mo after transplant. Transbronchial biopsy may confirm the diagnosis. Bronchial and/or tracheal anastomosis dehiscence is a problem. Infection remains a serious threat, and prophylactic treatment with trimethoprim-sulfamethoxazole (for *Pneumocystis carinii*), fluconazole (for fungus), and ganciclovir (for cytomegalovirus [CMV]) are used by some centers. Bronchiolitis obliterans occurs in 25–50% of survivors and is diagnosed with lung biopsies and treated with pulse steroids and other immunosuppressive agents (see Chapter 378). It may require re-transplant.

Heart-Lung Transplantation (see Chapter 435.2).

Postoperatively, these children require mechanical ventilation with the minimum possible intra-airway pressures, because high pressures increase stress on the tracheal suture lines. Fiberoptic bronchoscopies may be needed to clear potential obstructions. For 2–3 wk the denervated lung is sensitive to exogenous fluid overload and is prone to develop pulmonary edema. Rejection of the lung also may occur without evidence of cardiac rejection. This can be assessed with pulmonary function studies that demonstrate alterations in flow patterns, specifically FEF_{25-75} . Bronchoscopy with lavage and biopsies may also be useful in diagnosing rejection. Deaths in the perioperative period are often caused by uncontrollable hemorrhage.

Kidney Transplantation (see Chapter 528).

The goal in the immediate postoperative period is to encourage graft organ function; in children, this is achieved by maintaining renal perfusion with high levels of preload fluids producing substantial urine output. Even in the youngest children, the goal is to produce several hundred milliliters of urine per hour. Fluid replacement usually consists of normal saline or another physiologic fluid. This not only encourages sufficient urine production but also helps reduce the risk of thrombi at the vascular suture lines. Urine and insensible losses are replaced, and electrolytes are monitored closely. Blood pressure is tolerated at levels 20–30% higher than normal, particularly if a small child has received a transplanted adult kidney. The large fluid infusions when associated with a capillary leak phenomenon can produce significant pulmonary edema and necessitate meticulous respiratory management.

Ultrasound and Doppler flow studies of the newly transplanted kidney are often performed to confirm proper renal blood flow and to evaluate potential obstructive problems related to the surgery. When oliguria occurs, additional fluid replacement is instituted, assuming that the cause of oliguria is intravascular depletion. If oliguria persists in the presence of adequate intravascular fluid, then a range of problems, from obstruction of the Foley catheter to kinking of the implanted ureter, must be considered. If no fluid or mechanical cause can be found, early rejection or acute tubular necrosis may be the problem. Diuretics may be helpful (a continuous furosemide drip is often effective), but if the problem persists, a graft biopsy may be indicated. Postoperative hypertension should not be treated with angiotensin-converting enzyme inhibitors, because their site of action (at the glomerular arterioles) may jeopardize

---

glomerular perfusion. The treatment of rejection is discussed in Chapter 528 .

Liver Transplantation (see Chapter 349).

The most common indication for liver transplantation is biliary atresia. Additional indications include other congenital causes of cirrhosis, several inborn errors of metabolism (tyrosinemia, Wilson disease), toxic ingestions (acetaminophen overdose, mushroom poisoning), various forms of acute and chronic hepatitis, certain isolated nonmetastatic liver malignancies, and liver trauma. Management of transplantation and immunotherapy are discussed in Chapter 349 .

Hepatic failure results in various life-threatening conditions, including acidosis, coagulopathy, hyperammonemia and hepatic coma, hypoalbuminemia and anasarca, and portal hypertension with varices. Hyperammonemic hepatic coma may accelerate the consideration of transplant because it produces unconsciousness and apnea. Children having fulminant hepatic failure should be in a PICU at a liver transplant center for rapid evaluation and transplantation.

The liver graft is subject to an array of potential problems after transplantation. Hyperacute graft rejection is very rare but may occur within minutes of revascularization of a transplanted organ. The organ must be removed and replaced. Acute rejection can occur within the first 5–7 days after transplant and is manifested by rising levels of liver enzymes, worsening coagulopathy, and hepatic encephalopathy. It can be treated with high doses of steroids, increased doses of cyclosporine, or tacrolimus and, if these fail, antithymocyte antibody preparations. Vascular anastomosis breakdown produces hemorrhage and requires surgical re-exploration. Thrombus formation deprives the liver of blood flow and also requires surgery. Hematobilia may require surgical exploration. Intestinal perforations may occur and can be detected by observation of free air in the abdomen. Various abscesses and other fluid accumulations may need surgical exploration. Nonsurgical problems include hypertension (from fluid overload, steroid treatment, cyclosporine); pulmonary edema secondary to fluid overload; effusions; phrenic nerve injury producing basilar atelectasis; seizures; and coagulopathy. Extensive blood product administration may lead to metabolic alkalosis (from the citrate in blood products). Various electrolyte disturbances are possible and require monitoring of electrolytes. The kidney may manifest a mild form of acute tubular necrosis resulting from

necessary intraoperative occlusion of the inferior vena cava.

At the time of transplantation, children typically receive corticosteroids and either cyclosporine or tacrolimus. In some cases, small doses of antithymocyte globulin (ATG) or OKT3 are given as well. The early phase of immunosuppression extends for 2–3 wk postoperatively, and most patients continue lifelong small doses of steroids. Patients are also usually treated with antifungal (nystatin, fluconazole), anti-CMV (ganciclovir), and anti-*Pneumocystis* (trimethoprim-sulfamethoxazole, pentamidine) prophylactic medications for a limited time after transplant.

Intestinal Multiorgan Transplantation.

Pancreas, small bowel, liver, or various combinations of intestinal viscera transplantation are uncommon. These are experimental procedures for severe, intractable diseases unresponsive to any other form of therapy. In children, the most common reasons for considering intestinal viscera transplantation are short bowel syndrome caused by necrotizing enterocolitis, gastroschisis, volvulus, and intestinal atresias, with complete dependence on total parenteral nutrition.

Many postoperative risks are similar to those in other organ transplant operations. In addition, edema of intestinal tissues, and sometimes the inability to close the abdominal wall, may not allow rapid weaning from mechanical ventilation. Maintaining renal perfusion is critically important. Cleansing bowel preparations before surgery are advisable, as is postoperative treatment with enteral amphotericin, gentamicin, and polymyxin for several weeks. A short course of ganciclovir (for CMV prophylaxis) is usually also given, and patients may require prophylactic therapy with trimethoprim-sulfamethoxazole for life. Re-introduction of enteral feeding must be done very gradually, while continuing parenteral nutrition. Bowel transplants also should be assessed carefully for the signs and symptoms of bowel dysfunction: obstruction, abdominal tenderness, emesis, diarrhea, and melena. Endoscopic monitoring of the intestinal mucosa and monitoring fluid losses from ileostomy or colostomy sites are essential.

In the postoperative period, usually at the time of reperfusion of the implanted organs, steroids and tacrolimus or acyclovir are administered. Azathioprine may also be added. Prostaglandin E_1 is generally administered for 5–7 days to discourage the formation of clots in the microvasculature of the intestines and to dilate these vascular beds. Graft rejection usually results in fever, pain, distention, emesis, and increased stoma output. Severe rejection can lead to acute ulceration, perforation, and hemorrhage. Any evidence of biliary leakage or obstruction should be pursued vigorously. Vascular problems include microvascular thrombi and breakdown or large clots in vascular anastomoses. The risk of post-transplant infection and lymphoproliferative disease is greater than in other solid organ transplants.

Post-transplant Lymphoproliferative Disorders (PTLD).

PTLD involves the unregulated growth of lymphoid tissue, which may occur at sites where lymph nodes are ordinarily found or where nodes do not usually occur. The growing tissue may obstruct nearby structures and produce various symptoms. Stridor or wheezing can result from airway obstruction from the proliferation of mediastinal lymph nodes, adenoidal hypertrophy, or hypertrophy of the glottic structures. Dysphagia can occur when the gastric lymph nodes enlarge around the gastroesophageal junction. A bowel obstruction can occur if mesenteric lymph nodes enlarge and compress the bowel. In addition, PTLD may result in perforation of a hollow viscus, resulting in peritonitis and free air within the abdomen. The diagnosis may require endoscopy or surgical exploration to obtain tissue or relieve an obstruction. Treatment of PTLD involves reduction of immunosuppressive therapy. Adoptive immunotherapy against EBV may have value. Rarely, chemotherapeutic agents used in the treatment of lymphomas unassociated with transplantation are required (see Chapter 488).

Chapter 61 - Drowning and Near-Drowning

Harry J. Kallas

Childhood submersion is a common cause of injury and fatality. After submersion in a liquid medium, suffocation and asphyxia may occur, with or without pulmonary aspiration. Within a few minutes, hypoxia and ischemia can rapidly lead to irreversible multisystem injury and often to death. Treatment in the pediatric intensive care unit (PICU) has reduced mortality from the cardiorespiratory consequences of submersion events; however, neurologic injury from hypoxemia and ischemia is the primary cause of mortality and long-term morbidity.

Death within 24?hr of a submersion is termed *drowning*, which may be immediate or may follow resuscitation. Survival after more than 24?hr is termed *near-drowning*, regardless of whether the victim later dies or recovers. These definitions are somewhat arbitrary but are still widely used; there is no consensus on alternate nomenclature for submersion events.

Epidemiology.

Worldwide, it is estimated that 500,000 persons drown each year (approximately 1 person every min); the actual incidence is unknown, because many drowning deaths are not reported. The World Health Organization estimated the 1998 worldwide drowning mortality rate to be 8.4/100,000. As a cause of death globally, drowning ranked 11th for children younger than 5 yr old and 4th for children aged 5–14 yr.

Drowning is a major cause of injury death for children. Children younger than 5 yr old account for nearly 40% of all drowning fatalities. In 1–4 yr old children, drowning is the second leading cause of injury death in the United States and Africa and the leading cause in Australia and several U.S. states (Arizona, California, Florida, and Texas).

Fatality statistics convey only part of the problem, because many submersion victims are resuscitated and survive with neurologic sequelae. There are an estimated 500,000 significant submersions in the United States each year; 50,000 of these will require medical intervention. As many as 50% of all submersion victims are declared

dead at the scene and never present to medical facilities for care. Estimates of cumulative risk for males from birth to 19 yr of age indicate that 1/1,098 will drown, 1/301 will be hospitalized for near-drowning, and 1/75 will be treated or observed in an emergency department (ED); comparable risk estimates for females are 1/3,333, 1/913, and 1/228, respectively. Among children younger than 5 yr old, for every pediatric drowning victim there are 14.6 children hospitalized or seen in the ED with near-drowning. For California children (1994), there were 32.8 fatalities for every 100 hospitalized survivors of near-drowning. Of pediatric near-drowning victims treated at a tertiary care facility, 5–12% will survive with profound neurologic damage.

Risk factors for drowning include age, gender, and race. Drowning rates are highest in children younger than 5 yr old and second highest in 15–19 yr olds (predominantly adolescent males). In the United States (1995), 5% of children who drowned were younger than 1 yr old, 37% were 1–4 yr old, 15% were 5–9 yr old, 15% were 10–14 yr old, and 29% were 15–19 yr old. Male drowning victims predominate in all ages, accounting for 74% of drowning deaths; the male:female ratio increases dramatically from 2:1 in toddlers to over 10:1 in teenagers. In the United States, black children have almost double the overall drowning rate of white children. In Cape Town, South Africa, black children have triple the drowning rate of white children. For children older than age 5 yr in the United States, the relative risk of drowning in a swimming pool is 4- to 15-fold greater for black compared with white males and 3- to 10-fold greater for black versus white females.

The proportion of drowning at various sites is greatly influenced by the accessibility to various bodies of water, socioeconomic status, and geographic area. Any body of water can pose a hazard to the child; young children have drowned in a few centimeters of water, owing to their limited developmental abilities. In the United States (1995), 32% of all childhood drowning occurred in artificial pools, 9% occurred at domestic sites (mostly bathtubs), 47% occurred in natural freshwater (mostly rivers and lakes), and 4% occurred in saltwater. Almost 40% of drowning deaths happen during swimming.

The most common site of drowning varies depending on age. In the United States (1995), children younger than 1 yr old who drowned did so mostly in domestic sites (78%), predominantly in the bathtub, and fewer in artificial pools (14%). In drowning victims 1–4 yr old, 55% drowned in artificial pools and 26% died at natural freshwater sites. In most industrialized countries reporting drowning statistics, the swimming pool is the most common drowning site for young children. For U.S. children 5–9 yr old who drowned, 54% died in freshwater and 31% in artificial pools. In young adolescents (10–14 yr old) who drowned, 61% died in freshwater and 21% died in artificial pools. Older teenagers (15–19 yr old) drowned predominantly in freshwater sites (69%) and less commonly in artificial pools (12%) or saltwater (10%).

In warmer climates of the United States, Australia, and South Africa, 50–90% of drowning deaths occur in residential swimming pools; this site accounts for almost 90% of submersion events in children younger than 5 yr old. The U.S. Consumer Product Safety Commission estimated that 3,000 children younger than 5 yr old are seen annually in the ED after submersion in residential pools; up to 80% of these children are hospitalized for at least 1 day. Most pool submersion events occur at the child's own home, and nearly half occur within the first 6 mo of pool exposure. Brief lapses (<5?min) in supervision are associated with most submersion events.

In the United States, more than half of unintentional infant drowning occurs in the bathtub. Of all bathtub drowning, approximately 86% occur in children 7–15 mo old. After the first year of life, bathtub drowning becomes progressively less common (<10%). Often, these infants have inadequate supervision and parents who overestimate their child's abilities or coordination. In Japan, where bathtubs are commonly left filled with water, half of all drowning occurs in the bathtub, and this is the most common drowning site for children younger than 4 yr old.

Hot tubs and spas also pose special hazards, because many have suction devices that can entrap hair, clothing, or body parts, preventing children from surfacing. Brief lapses in supervision are noted in most circumstances; however, drowning from entrapment may occur even when the parents are present and directly supervising the child. Children younger than 2 yr old are the most frequent victims.

Children may also drown in buckets, toilets, washing machines, sinks, and other common house areas containing water. Young children fall headfirst into these water containers and may not be able to extricate themselves because of their relatively cephalad center of gravity and/or insufficient body mass to tip it over. Bucket drowning is common, constituting up to 24% of all toddler drowning in some regions; mortality is high, in part because of cleaning fluids and other caustic substances that buckets may contain.

In older children and teenagers, as much as 70% of drowning occurs in open bodies of water, such as lakes, ponds, streams, ocean beaches, or irrigation ditches, usually where little or no adult supervision exists. The U.S. Lifesaving Association reported 62,747 rescues on U.S. beaches in 1996; there was approximately an 8:1 ratio of near-drowning rescues to drowning

---

deaths. One fifth of open-water drowning events involve boats or other watercraft, and over 50% are associated with alcohol or drug use.

The risk of drowning is increased by the use of alcohol or illicit drugs. Alcohol clouds judgment, increasing the likelihood of injudicious risk-taking behavior, and retards motor coordination. Intoxicated adults are also incapable of providing adequate supervision for younger children near water. In a U.S. survey, 70% of males and 66% of females reported using alcohol during the preceding year while participating in aquatic activities; the largest group of positive respondents was 16–20 yr old. Positive blood alcohol levels are found in 10–50% of adolescent drowning victims.

Concomitant medical conditions may also increase the likelihood of drowning. Children with epilepsy have a 4- to 13-fold increased risk of drowning or near-drowning compared with nonepileptic children. Indeed, drowning is the most likely cause of unintentional injury death in this population. Epilepsy-associated drowning occurs predominately in bathtubs or swimming pools (86%); the majority of cases are in children older than age 5 yr. In nonepileptic children, other mental or motor disabilities may also increase drowning risk.

Child abuse or homicide by submersion does occur and requires a careful history, a high index of suspicion, and an understanding of normal childhood developmental capabilities. Child abuse or neglect may be a factor in 5–19% of submersions in children 1–4 yr of age and in 10–67% of bathtub-related events. Approximately 1 in 30 child homicides is by intentional drowning, mostly in the bathtub; 85% of intentional bathtub drowning involves children 15–30 mo old. Compared with unintentional injuries, victims of abuse are less likely to have resuscitation attempted by bystanders and are more likely to die.

Pathophysiology.

It is a common misconception that the submersion victim will signal their distress or call for help. In truth, most pediatric victims drown silently. Studies indicate that young children can only struggle for 10–20?sec before a final submersion event occurs. Indeed, the efforts of a drowning victim to breathe or their splashing may be misconstrued by nearby persons as mere “playing” in the water.

Once submersion occurs, all organs and tissues are at risk for hypoxia. In a short period, hypoxia can lead to cardiac arrest, adding ischemia to the succession of hypoxia-associated injury. The combination of hypoxia and ischemia is a common injury mechanism associated with submersion events, with the severity of injury dependent on the duration. Pulmonary aspiration can further exacerbate hypoxia and subsequent respiratory failure. Some victims may develop hypothermia, which is usually detrimental if not rapidly corrected. In some cases, a fatal catecholamine-induced arrhythmia secondary to one form of the prolonged QT syndrome is responsible for the cardiac arrest and death. In these cases, death does not result from aspiration or suffocation (see Chapter 428.4).

ANOXIC-ISCHEMIC INJURY.

After experimental submersion, a conscious animal will initially panic trying to surface. During this stage, small amounts of water enter the hypopharynx, triggering laryngospasm. Most animals struggle violently and swallow copious amounts of water. They soon lose consciousness from hypoxia. Vomiting may ensue, accompanied by involuntary gastric fluid aspiration. In about 10% of animals, the initial laryngospasm persists until death without aspiration into the lungs (aspiration is absent in 10–15% of humans who drown). Profound hypoxia and medullary depression lead to terminal apnea. During these events, cardiovascular changes include an initial tachycardia followed by severe hypertension with reflex bradycardia, presumably from intense catecholamine release; arrhythmias may be seen. By 3–4?min, the circulation abruptly fails as myocardial hypoxia supervenes. The heart may continue to have ineffective contractions or electrical activity for a short time, but there is no effective perfusion. The chance of successful resuscitation quickly becomes impossible as hypoxia and ischemia cause rapid, progressive, and irreversible injury.

The diving reflex may potentially enhance cerebral and myocardial blood flow when the face is submerged in very cold water (<20°C) and is believed by some to contribute to cerebral protection during submersion. Although this reflex is prominent in many sea mammals, it is relatively weak in humans. The extent of neurologic protection afforded humans by the diving reflex is controversial but is probably small.

All organs may be injured from hypoxia and ischemia, but the brain is exquisitely sensitive to hypoxic-ischemic injury. With intensive care, the cardiorespiratory consequences of resuscitated near-drowning are usually manageable and less often the cause of mortality compared with irreversible hypoxic-ischemic central nervous system (CNS) injury. CNS injury is the most frequent cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury occurs is uncertain, it is probably on the order of 3–5?min.

Myriad pathophysiologic events occur in the CNS as a result of hypoxemia and ischemia (see Chapter 57.7). The brain has minimal energy stores and requires constant delivery of oxygen and nutrients. After approximately 2?min of anoxia, adenosine triphosphate (ATP) is critically depleted. ATP is necessary to maintain neuronal metabolic functions and ionic gradients; its depletion is a likely trigger for a number of pathogenic cascades.

After cardiopulmonary arrest, cerebral blood flow (CBF) aberrations and impaired autoregulation may persist after resuscitation. After 15?min of global ischemia in dogs followed by the restoration of circulation, there initially is increased CBF (cerebral hyperemia) lasting 15–30?min, followed by delayed hypoperfusion lasting hours to days. This hypoperfusion may or may not be matched to cerebral metabolic demands. The uncoupling of CBF autoregulation to CNS metabolic demands increases the potential of further injury as cerebral metabolic rate of oxygen utilization returns to normal after the ischemic period while CBF remains low.

Secondary CNS injury during reperfusion occurs by various pathways. Injury is exacerbated by the release of glutamate and other “excitatory” amino acids. Glutamate is the predominant excitatory neurotransmitter of the brain and acts through specific receptors: the three principal ionophore-linked receptors are *N*-methyl-d-aspartate (NMDA), a-amino-3-hydroxy-5-methyl-4-isoxazol-eproprionic acid (AMPA), and kainate receptors. Activation of these receptors on neural cell membranes leads to an influx of calcium and sodium. Glutamate also acts on metabotropic receptors, which trigger secondary messenger systems and lead to release of calcium from intracellular stores. Increased intracellular calcium after hypoxia-ischemia is likely a final pathway toward irreversible cellular injury and death.

Alteration of calcium homeostasis can perpetuate numerous deleterious responses, including activation of phospholipases, proteases, endonucleases, protein kinases, and nitric oxide synthase, and the uncoupling of oxidative phosphorylation. Membrane phospholipid hydrolysis and the release of arachidonic acid metabolites contribute to oxygen free radical generation, the inflammatory response, and cellular damage. The brain is especially vulnerable to injury from free radicals, including superoxide, hydrogen peroxide, peroxynitrite, and nitric acid. Other important contributors to oxygen radical formation include cyclooxygenase, lipoxygenase, purine degradation, the electron transport chain, and inflammatory cells. Oxygen radicals produce cellular injury by various mechanisms, but most importantly lead to lipid peroxidation; the ensuing chain reaction produces more radicals, affects enzymatic function, compromises cell membrane integrity, interrupts DNA synthesis, and disrupts the blood-brain barrier. Additionally, the release of leukotrienes, tumor

necrosis factor, metalloproteases, kinins,

and other cytokines and mediators also injure the blood-brain barrier. The uncoupling of oxidative phosphorylation and the membrane disruption contribute to mitochondrial and cellular energy failure. A number of triggers for programmed cell death (apoptosis) are also activated, although its contribution to overall CNS injury after hypoxia-ischemia is still not clear.

After cardiopulmonary arrest, cerebral edema may occur. The mechanisms causing cerebral edema are not completely elucidated but are likely mostly due to swelling in astrocyte foot processes and, to a lesser degree, vasogenic edema from disruption of the blood-brain barrier. Astrocyte-mediated uptake of glutamate from the extracellular space appears to be coupled to sodium and water accumulation. Acidosis, potassium, and arachidonic acid also mediate astrocyte swelling. The traditional concept of “cytotoxic” cerebral edema due to cellular energy failure (the pump-leak model) is incomplete, although inability to maintain ionic gradients may still play some role in the production of cerebral edema. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; however, the very presence of ICP is an ominous sign of profound CNS damage.

Hyperglycemia after hypoxia-ischemia may also exacerbate CNS injury. After near-drowning, children with initial serum glucose concentrations of more than 250?mg/dL are more likely to die or survive in a persistent vegetative state compared with normoglycemic victims. Brain-injured hyperglycemic rats have greater CNS damage than injured normoglycemic rats; correction of hyperglycemia with insulin improves CNS outcome to a level equivalent to injured normoglycemic controls. Hyperglycemic rats have significantly lower CNS levels of adenosine and its metabolites compared with normoglycemic animals. Adenosine, proposed to be an endogenous neuroprotecter, causes regional cerebral vasodilatation, inhibits excitotoxin release, decreases calcium conductance, and affects neutrophil-endothelial interactions. Control of hyperglycemia with insulin after near-drowning cannot yet be recommended in humans until clinical trials are performed. It seems prudent to avoid iatrogenic hyperglycemia or hypoglycemia.

Other organs and tissues may also be injured by hypoxia-ischemia. In the lung, damage to pulmonary vascular endothelium, increasing vascular permeability, can lead to acute respiratory distress syndrome (ARDS, see Chapter 58). Aspiration compounds pulmonary injury (see Chapter 380). Myocardial dysfunction, arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute tubular necrosis or cortical necrosis are common renal complications of major hypoxic-ischemic events (see Chapter 57.5). Vascular endothelial injury can initiate disseminated intravascular coagulation (DIC, see Chapter 474), hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage, including hypoxia-ischemia, hypothermia, catecholamine infusions, and perhaps the diving reflex; a bloody diarrhea with mucosal sloughing may be seen after severe hypoxic-ischemic events and often portends a fatal injury. Levels of hepatic transaminases and serum pancreatic enzymes are often acutely elevated. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

ASPIRATION AND PULMONARY INJURY.

Pulmonary aspiration occurs in the great majority of drowning and near-drowning victims, but the amount aspirated is usually small. Nonaspirating victims may acutely succumb from laryngospasm and the consequences of hypoxia. The amount and composition of the aspirated material can affect the patient's clinical course: gastric contents, water salinity, pathogenic organisms, toxic chemicals, and other foreign matter can injure the lung or cause airway obstruction. A few children may have massive aspiration, increasing the likelihood of severe pulmonary dysfunction.

Clinical management is not significantly different in seawater or freshwater aspiration. Seawater is hypertonic (approximately 3% normal saline), establishing an osmotic gradient drawing interstitial and intravascular fluid into the alveoli; furthermore, seawater inactivates surfactant, increasing alveolar surface tension, making the alveolus unstable and prone to atelectasis. On the other hand, hypotonic freshwater aspiration washes out surfactant, also causing alveolar instability and collapse. In either case, hypoxemia and pulmonary insufficiency result from ventilation-perfusion mismatch, increased intrapulmonary shunting, decreased lung compliance, and increased small airway resistance. Profound hypoxia in experimental animals may be seen within 3?min after the aspiration of as little as 2.2?mL/kg. In humans as well, the aspiration of 1–3?mL/kg can lead to marked hypoxemia and a 10–40% reduction in lung compliance.

Pulmonary edema or ARDS may develop from aspiration of liquid or foreign material, hypoxia-ischemia, or marked hypothermia. In some cases, pulmonary edema may be cardiogenic (due to severely impaired myocardial function) or, uncommonly, neurogenic. Pneumonia may result from aspirated contaminated material. Gastric acid or caustic agent aspiration can directly injure the lung without infection being present. Ventilator-associated lung injury (see Chapter 57.4) can also occur with excessive tidal volumes or pressures or prolonged exposure to high concentrations of oxygen.

FLUID AND ELECTROLYTE ALTERATIONS.

The great majority of submersion victims do not aspirate large enough volumes of fluid to result in significant electrolyte disturbances. Many do swallow copious amounts of fluid, but even this does not appear to lead to a significant incidence of clinically relevant fluid or electrolyte aberrations. Children who survive long enough to be seen in the ED rarely have electrolyte aberrations requiring therapy.

Rarely, massive seawater ingestion or aspiration can lead to hypernatremia and fluid shifts because of its high sodium concentration and osmolarity. As fluid is osmotically drawn into the lungs or gastrointestinal tract, hemoconcentration may be observed. However, hypernatremia and hemoconcentration due to hyposmolar diuresis also occurs in diabetes insipidus (see Chapter 552), usually a sign of profound CNS injury after hypoxic-ischemic events.

Seldom, water intoxication can occur with massive freshwater aspiration or ingestion, causing hyponatremia and hemodilution. Sudden hyposmolarity can result in red

blood cell swelling and hemolysis, hypothetically leading to hemoglobinuria with renal tubular damage and hyperkalemia with subsequent VF. Plasma-free hemoglobin levels in human near-drowning are typically less than 500?mg/dL, usually insufficient to cause renal dysfunction from this mechanism alone. Alternatively, free water overload may be seen with excess antidiuretic hormone (SIADH), which can accompany pulmonary or brain injury (see Chapter 553.1). Excess free water can also increase cerebral edema and ICP.

HYPOTHERMIA

(see Chapter 63). Hypothermia (core temperature of less than 35°C) is common after submersion. Children are at increased risk of developing hypothermia owing to their relatively high body surface area to mass ratio, decreased subcutaneous fat, and limited thermogenic capacity. Hypothermia can develop as a result of prolonged surface contact with cold water and potentially after swallowing or aspirating large quantities of very cold fluid. Further drops in body temperature occur after the child is removed from the water as a result of cold air, wet clothes, hypoxia, and hospital transport.

Compensatory mechanisms will usually attempt to restore normothermia at body temperatures above 32°C; below this temperature, thermoregulation fails and spontaneous rewarming will not occur. Moderate hypothermia (core temperature 32–35°C) increases oxygen consumption owing to shivering thermogenesis and increased sympathetic tone. Below 32°C (severe hypothermia), shivering ceases and the cellular metabolic rate

decreases approximately 7% per °C in the absence of active thermogenesis.

With moderate to severe hypothermia, progressive bradycardia, impaired myocardial contractility, and loss of vasomotor tone contribute to inadequate perfusion, hypotension, and possible shock. Below 28°C, extreme bradycardia is usually present and the propensity for spontaneous VF or asystole is high. Central respiratory center depression with moderate to severe hypothermia results in hypoventilation and eventual apnea. Deep coma with fixed and dilated pupils and absent reflexes at very low body temperatures (<25–29°C) may give the false appearance of death.

Depending on the duration and severity of the temperature aberration, other systemic adverse consequences of hypothermia may occur acutely and persist even after rewarming. ARDS secondary to hypothermia can be seen in the absence of submersion or aspiration. Depressed hepatorenal metabolism and perfusion reduce drug clearance. Either hypoglycemia from glycogen store exhaustion or hyperglycemia due to catecholamines, altered pancreatic insulin release, and depressed peripheral glucose utilization may be observed. Thrombocytopenia, platelet dysfunction, and DIC also occur. Although hypothermia slows bacterial replication, it also renders the host more susceptible to bacterial and fungal invasion and sepsis by impairing neutrophil and reticuloendothelial function. Hypothermia must be expediently corrected to minimize such adverse consequences.

During initial rewarming efforts, core body temperature may initially decline. This *afterdrop* may occur secondary to the return of colder blood from the extremities to the relatively warmer central core or by the conduction of heat from the warmer core to cooler surface layers. In patients with severe hypothermia, afterdrop may further compromise cardiac, respiratory, or neurologic function or induce arrhythmias. Afterdrop in moderate to severely hypothermic victims may be mitigated if rewarming measures are not applied to the extremities, focusing efforts instead on core rewarming.

Rewarming shock may be observed after rescue. When subjected to the additional metabolic requirements of increasing body temperature and the vasodilatation accompanying surface rewarming, victims with borderline myocardial function may not be able to meet the increased physiologic demands. Hypotension, metabolic acidosis, tissue ischemia, and other consequences of shock (see Chapter 57.2) may therefore be exacerbated during rewarming.

Controversial Issues Related to Hypothermia. The implications and consequences of moderate to severe hypothermia in near-drowning victims are controversial. Misconceptions are fueled by a few case reports of dramatic neurologic recovery after prolonged (10–150?min) icy water submersion. There should be a clear distinction between “cold” and “ice” water. The rare survivor of a prolonged submersion typically has been in freezing water (<5°C) and has a core body temperature less than 30°C (usually much lower). Although hypothermia may confer a degree of cerebral protection from hypoxic-ischemic injury in controlled clinical situations (e.g., the operating room) and in rare individual near-drowning victims, many studies indicate that hypothermia is often a poor prognostic sign.

For hypothermia to be protective, core body temperature must fall extremely rapidly, decreasing cellular metabolic rate before hypoxia-ischemia leads to irreversible injury. Hypothermia has been shown to be effective in protecting the brain and other organs from hypoxia-ischemia for 75–110?min in controlled circumstances in which core body temperature is first cooled to 18°C and then the heart is stopped. However, once processes leading to cell death from hypoxia-ischemia have begun (starting at about 5–6?min), hypothermia does not confer a protective effect or improve recovery.

Surface cooling alone is unlikely to decrease body temperature fast enough to afford neuroprotection. The cooling rate of near-drowning victims is difficult to estimate, because, in addition to surface cooling, victims may swallow or aspirate water. Surface cooling of anesthetized infants with ice packs and ice water decreases rectal temperature by as little as 2.5°C in the first 10?min; it takes a further 32?min for the temperature to fall to 24–26°C. Therefore, hypothermia involving surface cooling would seem to require that prolonged submersion occur in icy water and that the victim continue breathing with the head above water as body temperature gradually cools. This situation is not commonly witnessed.

The hypothesis that the aspiration of icy water accelerates cooling is controversial. Most animals and human submersion victims in warm or cold water drowning aspirate very little. Theoretically, for sufficiently rapid neuroprotective-level hypothermia to develop, a very large quantity of icy water would have to be aspirated

or swallowed, or the victim would have to rebreathe a smaller quantity of water for a period of time. In human adults and animals, immersion in icy water results in intense involuntary reflex hyperventilation and a decreased breath-holding ability to less than 10?sec. Thus, it may be that victims of ice-water submersions are more likely to have involuntary respiration and a greater likelihood of aspiration or fluid rebreathing. In such a case, it may be possible for the brain to rapidly cool to a protective level (<30℃) provided that the water aspirated is icy and cardiac output lasts long enough for sufficient heat exchange to occur. Whether this scenario actually occurs is not known.

Hypothermia in non–icy water near-drowning is most commonly an unfavorable prognostic sign. In King County, Washington, where the water is cold but rarely icy, hypothermic protection has not been observed: 92% of survivors with good neurologic outcomes had initial temperatures greater than 34℃, whereas 61% of those who died or had severe neurologic injury had temperatures less than 34℃. Similarly, in Finland where the median water temperature was 16℃, a beneficial effect of hypothermia could not be proved in pediatric submersion victims; submersion duration less than 10?min was most related to good outcome.

Clinical Manifestations and Treatment.

A submersion victim's clinical course and outcome are primarily determined by the circumstances of the incident, the duration of submersion, the speed of the rescue, and the effectiveness of resuscitative efforts. Two groups may be identified based on responsiveness at the scene. Children who require minimal amounts of resuscitation at the scene commonly have good outcomes and experience a low incidence of complications. These victims quickly regain spontaneous respiration and typically regain consciousness rapidly. They should be transported to the ED for further evaluation.

Victims in cardiac arrest require aggressive or prolonged resuscitation and have a high risk of multiorgan system complications, major neurologic morbidity, or death. Initial management requires coordinated and experienced prehospital care following the “ABCs” of emergency resuscitation (see Chapter 51). These children often remain comatose and lack brainstem reflexes despite the restoration of oxygenation and circulation. Subsequent ED and PICU care often involves advanced life support strategies and management of multiorgan dysfunction.

INITIAL EVALUATION AND RESUSCITATION (see Chapter 57.1).

Once a submersion has occurred, extrication and immediate institution of cardiopulmonary resuscitative efforts at the scene are imperative. Every minute that passes without the re-establishment of adequate breathing and circulation dramatically decreases the possibility of a good outcome. In near-drowning victims with cardiac arrest who receive prehospital CPR, only 7–21% will have neurologically intact survival. Children with good outcomes are almost five times as likely to have had immediate scene resuscitation compared with children with poor outcomes, although this is not demonstrated in

all series. Waiting for the arrival of paramedics should not delay bystander resuscitative efforts; even in a model prehospital system, the arrival of paramedics takes longer than 10?min in 91% of submersion cases.

Initial resuscitation must focus on rapidly restoring oxygenation, ventilation, and adequate circulation. The airway should be clear of vomitus or foreign material, which may result in obstruction or aspiration. Abdominal thrusts should not be used for lung fluid removal, as their effectiveness is not established; because many victims have a distended abdomen from swallowed water, abdominal thrusts may increase the risk of regurgitation and aspiration. In cases of suspected airway foreign body, chest compressions or back blows are preferable maneuvers.

The cervical spine should be protected in anyone with potential neck injury (see Chapter 57.8), such as in child abuse, water sport accidents, diving injury, or unknown circumstances surrounding the immersion. The neck should be in a neutral position and protected with a well-fitting cervical collar. Fortunately, neck injuries in submersion victims are uncommon. Approximately 0.5% of submersion victims have cervical-spine injuries. Victims with spine injuries have a history of diving, motorized vehicle crash, fall from height, or submersion in open bodies of water and clinical signs of serious injury. Spinal injuries are exceedingly rare in low-impact submersions.

If the victim has ineffective respiration or apnea, ventilatory support must be initiated immediately (see Chapter 57.1). Mouth-to-mouth or mouth-to-nose breathing by trained bystanders often restores spontaneous ventilation. As soon as it is available, supplemental oxygen should be administered to all victims. Positive pressure bag-mask ventilation with high inspired oxygen concentration should be instituted in patients with respiratory insufficiency.

Gastric distention is often exacerbated by mouth-to-mouth or bag-mask ventilation. Vomiting is seen in 25–75% of victims during resuscitation, and nearly 25% aspirate their gastric contents. Cricoid pressure (the Sellick maneuver) during positive pressure breathing and early nasogastric decompression may decrease the risk of vomiting and aspiration (see Chapter 57.1).

If apnea, cyanosis, hypoventilation, or labored respiration persists, trained personnel should perform endotracheal tube (ETT) intubation as soon as possible. Intubation is also indicated to protect the airway in patients with depressed mental status or hemodynamic instability. Hypoxia must be corrected to optimize the chances of recovery. Oxygen alone may not correct hypoxia in patients with significant pulmonary edema or aspiration; in such cases, the application of positive end-expiratory pressure (PEEP) is necessary to decrease intrapulmonary shunt and improve oxygenation. The routine use of PEEP in near-drowning has made early death from pulmonary insufficiency uncommon. Initial PEEP should be about 5?cm H_2O; it can be increased incrementally up to 10–15?cm H_2O if oxygenation remains inadequate (goal SaO_2 > 90%). During bag-ETT ventilation, PEEP can be maintained by using an adjustable PEEP valve. Tidal volume and breath frequency should initially attempt to achieve normal ventilation without contributing to lung

injury. Attempts to acutely or aggressively hyperventilate victims may be harmful.

Concurrent with securing airway control, oxygenation, and ventilation, the child's cardiovascular status must be evaluated. Heart rate and rhythm, blood pressure, temperature, and end-organ perfusion require urgent assessment. CPR should be instituted immediately in pulseless, bradycardic, or severely hypotensive victims (see Chapter 57.1). ECG monitoring assists with the diagnosis and treatment of arrhythmias. Slow capillary refill, cool extremities, or altered mental status are potential indicators of shock (see Chapter 57.2). Core temperature must be evaluated, especially in children, because moderate to severe hypothermia can depress myocardial function and cause arrhythmias.

Often, intravenous fluids and cardioactive medications are required to improve circulation and perfusion (see Chapter 57.1). Venous access should be established as quickly as possible for the administration of fluids or pressors. In many cases, intraosseous catheter placement is a potentially lifesaving vascular access technique that avoids the delay usually associated with multiple attempts to establish intravenous access in critically ill children (see Chapter 57.1). Epinephrine is usually the initial drug of choice in victims with cardiopulmonary arrest (initial IV dose is 0.01?mg/kg of 1:10,000 solution; subsequent IV doses may be as high as 0.1?mg/kg of 1:1000 solution). Epinephrine can be given intratracheally (ETT dose is 0.1–0.2?mg/kg of 1:1,000 concentration) if no intravenous access is available. Bolus intravascular administration of lactated Ringer solution or normal saline is often used to augment preload.

In children with cardiac arrest after submersion, the first recorded rhythm is asystole in 55%, ventricular tachycardia (VT) or VF in 29%, and bradycardia in 16%. Electrical defibrillation or cardioversion is urgently necessary for children with VF or pulseless VT (see Chapter 57.1); other cardioactive medications may be necessary to restore a perfusing rhythm (see Chapter 57.1). Post-resuscitation catecholamine infusions may be required to augment myocardial function and support blood pressure (see Chapters 57.1 and 57.2).

Attention to hypothermia in the field is very important, both to initiate rewarming measures and to prevent the consequences of deeper hypothermia. A low recording thermometer and a high index of suspicion are required to diagnose hypothermia. Core temperature is best measured at the tympanic membrane; rectal temperature determinations are often inadequate, owing to insufficient thermometer insertion depth; oral and axillary temperature readings are unreliable. All hypothermic victims should have damp clothes removed, the skin dried, warm blankets applied, and a warm environmental temperature provided as soon as possible. If available, warmed intravenous fluids (40–43°C) and humidified oxygen (42–46°C) should be used, although their rewarming efficacy is not well established. For victims not in cardiac arrest with core temperatures less than 34°C, external rewarming measures should be applied only to truncal areas, attempting to avoid afterdrop. In poorly perfused hypothermic victims, the application of warm packs and other cutaneous rewarming devices may cause significant burns. Patients with severe hypothermia (core temperature less than 30°C) require active internal warming measures provided as soon as possible (see Chapter 63).

Assessment of blood glucose should be obtained in the field. If a child is hypoglycemic, 0.5–1?g/kg dextrose should be administered as either 10% or 25% solution (maximum: 25?g/dose). In hyperglycemic victims, dextrose-containing solutions initially should be withheld but repeated assessments must be made to avoid unrecognized subsequent hypoglycemia. Although some preliminary data suggest that correction of hyperglycemia may improve outcome, the use of insulin cannot yet be generally recommended for correction of hyperglycemia after submersion injury.

Controversial Issues in the Resuscitation of Severely Hypothermic Victims. The cardiorespiratory management of patients with very severe hypothermia (temperature 28°C) is controversial. Ventricular arrhythmias have been temporally associated with ETT intubation or chest compressions in occasional reports of severely hypothermic patients. Therefore, some authors advocate withholding intubation or chest compressions if any respiratory activity or perfusing rhythm is present to avoid precipitating VF. In a prospective study of severely hypothermic victims, ventricular arrhythmia associated with ETT intubation was not observed. Therefore, gentle ETT placement should be performed in children with hypoxia or insufficient respiration.

No prospective studies are available to guide the clinician regarding chest compressions in severely hypothermic victims

who are not in cardiac arrest. Some authors would withhold chest compressions if core temperature is less than 28°C and the electrocardiogram shows a perfusing rhythm with a pulse, regardless of heart rate or hypotension. The logic behind these recommendations follows from observations that effective perfusion often returns with rewarming; rewarming is more effective when any circulation is present; VF or asystole slows rewarming efforts; chest compressions may precipitate VF; cardiopulmonary resuscitation (CPR) is less effective during severe hypothermia. However, given the lack of clinical data, some practitioners would initiate CPR, attempting to thwart life-threatening compromises of cardiac output (see Chapter 63).

Full CPR with chest compressions is indicated for hypothermic victims if (1) narrow-complex QRS activity is absent on ECG or, (2) core temperature is unknown or more than 28°C (82.4°F), no ECG monitor is available, and a pulse cannot be found. When VF is present in severely hypothermic victims, up to three defibrillation attempts should initially be delivered; if defibrillation is unsuccessful, CPR should be reinstituted; some would minimize further defibrillation attempts until the child's temperature is more than 30°C (86°F), at which time successful defibrillation may be possible (see Figure 63–1).

Victims with profound hypothermia may appear clinically dead, but full neurologic recovery is possible, although rare. Attempts at lifesaving resuscitation should not be withheld based on initial clinical presentation unless the victim is obviously dead (e.g., dependent lividity or rigor mortis). Body temperature should be taken into account before resuscitative efforts are terminated. Rewarming efforts, in general, should be continued until temperature is at least 32–34°C (89.6–93.2°F); if the victim then continues to have no effective cardiac rhythm and remains unresponsive to

aggressive CPR, resuscitative efforts may be discontinued.

Complete rewarming is not indicated for all arrest victims. Some children with severe hypothermia and the appearance of death are actually dead. In most situations, discontinuing resuscitative efforts in victims of non–icy water submersions who remain asystolic despite 30–45?min of aggressive advanced CPR is probably warranted. Physicians must use their individual clinical judgment when deciding to stop resuscitative efforts, taking into account the unique circumstances of each incident.

HOSPITAL-BASED EVALUATION AND TREATMENT.

ED and hospital management of the submersion victim includes and extends the aforementioned resuscitative efforts. Again, patient acuity will determine the extent of further interventions. Some children will present to the ED alert and with minimal symptomatology. More ill children require hospitalization for ongoing evaluation and monitoring. Critically ill victims must be stabilized and admitted to a PICU.

All pediatric submersion victims probably should be hospitalized or observed for at least 8–12?hr, even if they are asymptomatic on presentation to the ED. At a minimum, serial monitoring of vital signs (respiratory rate, heart rate, blood pressure, and temperature); repeated careful pulmonary examination and neurologic assessment; chest radiography; and assessment of oxygenation by arterial blood gas or pulse oximetry should be performed on all submersion victims. Other studies may also be warranted depending on specific circumstances (e.g., possible traumatic injuries or suspected intoxication). Of initially asymptomatic children, almost half may become symptomatic, usually during the first 4–8?hr post-submersion. Mild to rarely severe delayed respiratory symptoms and pulmonary edema can occur even in children with initially normal chest examination and radiography. Among patients who do not require advanced life support in the prehospital setting or during their first 4?hr in the ED and have a Glasgow Coma Scale (GCS) score of 13 or greater on ED presentation, those who develop respiratory deterioration or oxygen desaturation are most likely to do so within 6?hr, if at all. Conversely, most children with minor early respiratory symptoms will become asymptomatic by 18?hr post-submersion. Usually, these children will have the return of normal room air oxygenation and pulmonary examination by 4–6?hr and are unlikely to have subsequent delayed respiratory deterioration. It appears that select low-risk patients who are alert and asymptomatic with normal examination and oxygenation may be considered for discharge after 8–12?hr of observation, as long as appropriate follow-up can be assured.

Respiratory Management. The level of respiratory support should be appropriate to the patient's condition and is a continuation of prehospital management. One must frequently reassess that adequate oxygenation, ventilation, and airway control are maintained. Supplemental oxygen should initially be provided to all victims. Increased inspired oxygen concentration (F_{IO_2}) alone may not resolve hypoxia, and ETT intubation and PEEP are often needed. PEEP increases functional residual capacity, decreases intrapulmonary shunting, improves ventilation-perfusion matching, and may improve pulmonary compliance. The level of PEEP and F_{IO_2} should restore oxygenation, usually to a goal Sa_{O_2} of more than 90%. Excessive PEEP can impair venous blood return and depress cardiac output. Prolonged use of high F_{IO_2} (>70–80%) may cause pulmonary oxygen toxicity. An arterial catheter is often required for reliable and frequent arterial blood gas assessment and continuous blood pressure monitoring in critically ill patients.

Unintubated alert children with mild to moderate hypoxemia despite supplemental oxygen who can protect their airway may be candidates for mask continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). These noninvasive measures can improve oxygenation and possibly avert ETT intubation. A nasogastric tube may be necessary to prevent gaseous gastric distention. Persistent hypoxemia, impaired ventilation, labored respiration, depressed mental status, or patient intolerance usually requires ETT intubation to secure the airway and breathing.

Hypercapnia should generally be avoided in potentially brain-injured children. Patients with actual or potential hypoventilation or marked elevated work of breathing should have assisted or controlled mechanical ventilation to avoid hypercapnia and decrease the energy expenditures of labored respiration. The usual initial ventilatory goal is a Pa_{CO_2} of 35–40?mm Hg. Excessive hyperventilation is not indicated; even moderate hyperventilation may potentially contribute to cerebral hypoperfusion.

Children with bronchospasm after near-drowning may benefit from β_2 -agonist therapy; however, pulmonary edema or airway foreign body may also cause wheezing and should be considered. Bronchoscopy is indicated if a foreign body is suspected. The routine use of diuretics or corticosteroids for pulmonary edema or lung injury is not recommended. Prophylactic antibiotics are not generally helpful, except in cases where aspirate is known to be grossly contaminated.

ARDS is a serious complication in some submersion victims (see Chapter 58). ARDS can have detrimental effects on oxygenation and pulmonary compliance. Patients administered high airway pressures or tidal volumes during mechanical ventilation are also at increased risk for ventilator-induced lung injury. Studies indicate that the application of peak airway pressures greater than 30–35?cm H_2O may lead to alveolar overdistention and damage, exacerbating lung injury, and promoting pulmonary and systemic inflammatory responses. The use of lower tidal volumes and pressures is associated with decreased ARDS mortality. Patients with ARDS and brain injury pose a difficult challenge because permissive hypercapnia—a strategy commonly employed in ARDS—is normally contraindicated in patients with brain injury or intracranial hypertension. Sedation and, less often, neuromuscular blockade may be necessary to improve thoracic compliance, patient-ventilator synchrony,

and gas exchange; these medications can obscure neurologic evaluation, making prognostication and decision-making more difficult.

Various modes of high-frequency ventilation have been successfully used in near-drowning victims failing conventional mechanical ventilation (see Chapter 57.4). In some cases, inhaled nitric oxide may help improve ventilation-perfusion matching and decrease pulmonary hypertension (see Chapter 57.4). Exogenous

surfactant after near-drowning has been tried, but indications for its use and guidelines for effective delivery in this population do not exist. Partial liquid ventilation has been performed in individual near-drowning patients with ARDS (see Chapter 58). Extracorporeal life support (ECLS) in near-drowning has been reported; however, the general application of ECLS in submersion victims is controversial and should be limited until better selection criteria and more accurate predictors of neurologic outcome exist.

Cardiovascular Management. Cardiovascular stabilization is a continuation of measures instituted in the prehospital setting. Causes contributing to myocardial insufficiency include hypoxic-ischemic injury, ongoing hypoxia, hypothermia, acidosis, high airway pressures during mechanical ventilation, alterations of intravascular volume, and electrolyte disorders. Heart failure, shock, arrhythmias, or cardiac arrest may occur. Continuous ECG monitoring is mandatory to recognize and treat arrhythmias. Arterial catheterization facilitates continuous blood pressure and laboratory monitoring. Echocardiography, central venous pressure monitoring, or pulmonary artery catheter placement may aid assessment of intravascular volume status and myocardial function.

The provision of adequate oxygenation and ventilation is a prerequisite to improving myocardial function. Fluid resuscitation and inotropic agents are often necessary to improve heart function and restore tissue perfusion. Increasing preload with intravenous fluids may be beneficial by improving stroke volume and cardiac output. Overzealous fluid administration, especially in the presence of poor myocardial function, can worsen pulmonary edema. Epinephrine infusion (dose range: 0.05–1?µg/kg/min) is usually the drug of choice for patients with cardiac dysfunction or hypotension after hypoxic-ischemic events. Others suggest that dobutamine (dose range: 2–20?µg/kg/min) may better improve cardiac output in normotensive patients. Some patients may require other drugs depending on specifics of their cardiovascular dysfunction (see Chapter 57.1). Electrolyte abnormalities, particularly hypocalcemia, and body temperature should be corrected to optimize myocardial performance.

Rewarming Measures (see Chapter 63). Patients with significant hypothermia, if rapidly rewarmed, may have improved stability and decreased morbidity. Adequate circulation greatly facilitates rewarming. Passive rewarming (e.g., warm room, dry blankets) relies on the patient's thermogenic ability and is not sufficient for most significantly hypothermic children. Active external rewarming (e.g., warm blankets, radiant warmers) restores temperature more rapidly (0.8 ± 0.4°C/hr), but decreased surface circulation makes this method less effective. Moderate sources of external heat (e.g., forced-air blanket at about 100?W) may result in skin rewarming and shivering inhibition, but there is little rewarming advantage compared with shivering itself. Placing the subject in a forced warm air box (400?W) produces rates of rewarming double that of shivering (6.1 vs. 3°C/hr).

Active core rewarming more rapidly improves body temperature and is necessary for moderate to severe hypothermia or for victims with impaired shivering thermogenesis. Simple active core rewarming measures include administration of warmed intravenous fluids (36–40°C) and heated humidified inspired oxygen (40–44°C), although the efficacy of these measures is controversial. Gastric, bladder, or peritoneal lavage with warmed saline may be instituted relatively easily. More aggressive methods include hemodialysis, extracorporeal rewarming (venovenous or arteriovenous), or cardiopulmonary bypass (CPB). Rewarming rates for extracorporeal rewarming (2.1 ± 0.7°C/hr) are significantly faster than external active rewarming methods. For profound hypothermia, especially if circulatory collapse is present, CPB may be required and has a very rapid rewarming rate (6.9 ± 1.9°C/hr). Indications for CPB are not well established; this complex decision requires physician anticipation and rapid transfer to a tertiary care center.

Neurologic Management. Near-drowning victims who present to the hospital awake and alert practically always have normal neurologic outcomes. In comatose victims, the possibility of irreversible CNS injury is a major concern. The primary injury, cell death from hypoxia-ischemia, is not currently treatable. Current therapy emphasizes reducing the duration of the primary insult (i.e., prompt resuscitation) and reducing the potential for secondary CNS injury.

The most effective neurointensive care measures in near-drowning are the rapid restoration of adequate oxygenation, ventilation, and perfusion. Unfortunately, studies of therapies aimed at controlling ICP or maintaining cerebral perfusion pressure have failed to clearly demonstrate improved outcome. Some general measures may be of benefit. Hypoglycemia and iatrogenic hyperglycemia should be avoided. Attempts to control seizures (see Chapter 57.7) and fever are warranted, because they increase cerebral metabolic activity and oxygen utilization. Other neurointensive care measures must be critically scrutinized, given that few have not been shown to improve satisfactory patient outcome after severe global hypoxic-ischemic injuries.

Head CT scans are not generally helpful unless there is a suspicion of associated traumatic injury or to rule out other possible causes of coma. The great majority of near-drowning victims initially have normal scans. An acutely abnormal CT scan is most frequently associated with death. After 24?hr, poor gray-white differentiation and cerebral edema may be seen in children with severe hypoxic-ischemic injuries. Head CT scans cannot adequately distinguish patients with good outcomes versus poor ones. MRI may detect changes associated with hypoxic-ischemic injuries earlier than head CT, but MRI is rarely clinically indicated. There is no advantage to head CT scans or MRI over neurologic examination for prognostication or management of nontraumatic near-drowning.

Many neurointensive care measures have been shown not to benefit the usual near-drowning victim. Although ICP monitoring and therapy to reduce intracranial hypertension would seem likely to preserve cerebral perfusion and prevent herniation, in fact, it does not appear to improve outcome for near-drowning victims. Patients with elevated ICP usually have poor outcomes—either death or persistent vegetative state—regardless of ICP management. Children with normal ICP can also have poor outcomes, although less frequently. Conventional neurointensive care therapies such as osmotic agents, diuretics, fluid restriction, muscle relaxants, hyperventilation, barbiturates, and steroids—measures often used in victims with elevated ICP from different causes—so far have not been shown to benefit the near-drowning victim either individually or in combination. Indeed, there is some evidence that these therapies may decrease overall mortality, but only by increasing the number of survivors in persistent vegetative state: they do not increase the number of neurologically intact survivors or reduce neurologic morbidity.

A number of potential therapies for hypoxic-ischemic brain injury are being studied.

Resuscitative or therapeutic cerebral hypothermia in experimental animals may improve neurologic outcome after moderate global hypoxic-ischemic injury; early human studies have shown variable results.

Two randomized controlled trials in a highly selected cohort of adults with out-of-hospital cardiac arrest indicated that early therpeutic hypothermia was associated with decreased mortality and neurologic morbidity. Whether these results are generally applicable to children with hypoxia-induced cardiac arrest (the predominant mechanism of arrest in submersion events) is unknown.

Anti-excitotoxic therapies in humans have not yet proved beneficial; in animals, they must be given within the first 1–2?hr to reduce neurologic injury. Other investigational therapies include oxygen radical scavengers; lipid peroxidation inhibitors; calcium channel antagonists; glutamate pathway antagonists; NMDA-, AMPA-, and GABA-receptor antagonists; glutamate release inhibitors; nitric oxide synthase inhibitors; strategies to improve CBF during delayed hypoperfusion; anti-apoptosis targeted strategies; and a re-investigation of barbiturates.

With optimal management, many initially comatose children can have dramatic neurologic improvement, which usually occurs within the first 24–72?hr. Unfortunately, almost half of deeply comatose children admitted to the PICU will die of their brain injury or survive with severe neurologic damage. Many children become brain dead (see Chapter 64); indeed, submersion injury is the second leading cause of brain death in the PICU. Deeply comatose near-drowning victims who do not substantially improve their neurologic examination by 24–72?hr of aggressive cardiorespiratory support and whose coma cannot be otherwise explained should be seriously considered for limitation of support (see Chapter 64).

Other Management Issues. Some submersion victims may have traumatic injury, especially if they were participating in water sports such as boating, diving, or surfing. A high index of suspicion is required. Spinal precautions should be maintained in victims with altered mental status and suspected traumatic injury. Significant anemia should raise suspicion of trauma and internal hemorrhage.

Hypoxic-ischemic injury can have multiple systemic effects, although protracted organ dysfunction is uncommon in the absence of severe CNS injury. Even after initially severe pulmonary injury, with careful supportive management, lung function returns to normal in most near-drowning victims. Acute renal failure after hypoxic-ischemic injury from acute tubular or cortical injury can result in proteinuria, glucosuria, hemoglobinuria, oliguria, or anuria. Diuretics, fluid restriction, and dialysis are uncommonly needed to treat fluid overload or electrolyte disturbances; renal function usually normalizes in survivors. Rhabdomyolysis after drowning has been reported. Profuse bloody diarrhea and mucosal sloughing usually portend a grim prognosis; conservative management includes bowel rest, nasogastric suction, and gastric pH control. Nutritional support for most near-drowning victims is usually not difficult, because the majority of children either die or recover quickly and resume a normal diet within a few days; enteral tube feeding or parenteral nutrition is occasionally indicated in children who do not quickly recover.

One third to half of near-drowning victims have a fever during the first 48?hr after their submersion. Fever resolves spontaneously without antibiotics in approximately 80% of patients. Prophylactic antibiotics are not recommended. Antimicrobial therapy should be considered in victims with persistent fever, worsening pulmonary or general clinical status, or other evidence of infection. Pulmonary or disseminated infection, either bacterial or fungal, can occur. Reported causes of near-drowning–associated pneumonia include several unusual pathogens, which are frequently specific to the drowning medium and geographic region. Sepsis in critically ill patients can also arise from nonpulmonary sources, requiring careful assessment. Early respiratory and blood cultures should be considered and infectious disease consultation obtained in unusual cases.

Severe anoxic encephalopathy is seen in 10–30% of PICU survivors after near-drowning. Chronic neurologic sequelae include lowered mentation, cerebral dysfunction, spastic quadriplegia, extrapyramidal syndromes, optic and cerebral atrophy, cortical blindness, peripheral neuromuscular damage, or persistent vegetative state.

Psychiatric and psychosocial sequelae are common. Grief, guilt, and anger are frequent. Divorce rates of up to 80% are reported within a few years of severe injury to children, and parents often report difficulties with employment or substance abuse. Friends and family may blame the parents for the event. Professional counseling, pastoral care, or social work referral should be considered for all near-drowning victims and their families.

Prognosis.

Overall, about 80% of pediatric submersion victims survive and 92% of survivors have a complete recovery. In those children requiring PICU care, about half survive neurologically intact, but 13–35% die and 7–27% survive with severe brain damage. The outcomes of near-drowning victims are remarkably bimodal: the great majority of victims either have good outcomes (intact or mild neurologic injury) or bad outcomes (persistent vegetative state or death), with very few exhibiting intermediate neurologic injury.

Accurate neurologic prognostication is important for the child, family, physicians, and society. Victims most likely to have good neurologic outcomes should be offered the most aggressive intensive care measures to prevent death from associated injuries; conversely, children with devastating neurologic injuries can be spared the futility of therapies that will not improve their condition. Early and precise prognostication is important to guide triage decisions, counsel families, reduce unnecessary interventions, guide discussions with families regarding limitation of support, and decrease the expenditure of valuable resources on children who will not recover.

Scoring and classification systems as well as individual factors have been used to predict near-drowning outcome. Although many of these systems strongly correlate with outcome, to date, none is accurate enough to completely differentiate good from poor outcomes. In many studies, several factors correlate with outcome, including (1) historical variables, such as submersion duration, interventions at the scene, and

patient temperature; (2) treatment variables, such as need for CPR in the ED, apnea and pulselessness, resuscitation duration, GCS and progression, pupillary responsiveness, and brainstem reflexes; and (3) laboratory values, such as pH and glucose.

Prehospital predictors of non–icy water immersion outcomes in King County, Washington, have been comprehensively evaluated (1974–1989). Intact survival or mild neurologic impairment occurred in 91% of children with submersion duration less than 5?min and in 87% who had resuscitation duration less than 10?min. Children at the scene with normal sinus rhythm, reactive pupils, or neurologic responsiveness virtually always had good outcomes (>99%). In cases requiring advanced CPR, death or severe neurologic injury occurred in 93% of patients with submersion duration more than 10?min and in 100% of victims requiring resuscitation for more than 25?min. All victims with submersion duration of more than 25?min died in this study. However, a few authors have rarely noted sporadic intact recovery in non–icy water near-drowning after longer submersion or resuscitation duration, highlighting the difficulty in assigning absolute prognostic classification based on prehospital and ED variables alone.

Other studies of pediatric non–icy water submersions indicate that only a third of victims requiring advanced CPR at the scene survive, but two thirds of survivors have good recoveries. In a study with 89 patients who received CPR in the ED, 41 (46%) survived (8/41 intact and 33/41 with persistent vegetative state). In victims requiring CPR in the ED, functional

recovery has been reported in only 0–24% (average 17%). Prolonged CPR after non-icy water submersion almost invariably predicts death or persistent vegetative state. Therefore, the discontinuation of CPR in the hospital is probably warranted for victims of non–icy water submersions who do not respond to aggressive advanced life support within 25–30?min. In any given victim, however, the circumstances surrounding submersion may not be known, especially during the first 25?min of an ongoing resuscitation; therefore, decisions regarding when to discontinue resuscitative efforts must be individualized, understanding that protracted resuscitation efforts generally will not result in survivors with a possibility of a good outcome.

The GCS (see Chapter 57.7) has some utility in predicting recovery. Children with a score of 6 or more on admission to the hospital generally have good outcomes, whereas those with a score of 5 or less have a much higher probability of poor neurologic outcome. However, some children with ED GCS of 3 or 4 uncommonly can have complete recovery. Upward trends in GCS during the first several hours of hospitalization may indicate a better prognosis. Overall, the GCS fails to adequately distinguish children who will survive intact from those with major neurologic injury.

Neurologic examination and progression during the first 24–72?hr are presently the best prognosticators of long-term CNS outcome. Children who regain consciousness within 72?hr, even after prolonged resuscitation, are unlikely to suffer serious neurologic sequelae. In a small series of comatose non–icy water submersion victims, all satisfactory survivors were noted to have spontaneous purposeful movements and normal brainstem function within 24?hr. Good recovery did not occur in any child with abnormal brainstem function and absence of purposeful movements at 24?hr. In another small series of near-drowning victims who remained unconscious more than 24?hr and survived at least 1 yr, 73% remained in a persistent vegetative state and the rest had severe neurologic impairment. These victims continued to have many complications and high mortality: 45% died during the study's post–1-year follow-up period.

The prognostic value of neurologic functional recovery during the first 72?hr of hospitalization was also observed in a larger retrospective series of 274 submersion victims (1985–1994). An initial ED GCS score of 3 was recorded in 100 patients; of these deeply comatose children, only 14% survived intact. There were 185 intact survivors, 95% of whom demonstrated functional recovery (time to first documented purposeful response) within 48?hr. In the 168 patients with a first documented purposeful response within 6?hr, all survived intact. Conversely, only 5.6% of children with poor outcomes (died or survived with persistent vegetative state) had “purposeful” movement within 48?hr. Of note, one child with good outcome and one with an intermediate outcome did not have purposeful movement until 1 and 3 mo, respectively.

Because of inexact prognostication in the prehospital setting and the ED, all near-drowning victims should receive appropriate aggressive support initially. Serial neurologic evaluation should be performed over the ensuing 48–72?hr with consideration of limitation of support in patients failing to demonstrate significant neurologic recovery, even though this may occur before absolute prognostic certainty is achieved.

Laboratory and technologic methods to improve prognostication have not yet proved superior to the neurologic examination. Methods that have received limited investigation include CT scans, MRI, electroencephalography, brainstem auditory evoked responses, somatosensory evoked potentials, visual evoked potentials, cerebrospinal fluid creatine kinase and lactate assays, measurements of CBF and cerebral metabolic rate, positron emission tomography, and magnetic resonance spectroscopy.

Prevention.

The best hope for a “cure” of drowning and its serious consequences lies in prevention. These efforts must focus on legislation as well as ongoing education of parents, children, and physicians. Unfortunately, too few physicians are an adequate resource. In a survey of pediatricians in the American Academy of Pediatrics (AAP), 85% of respondents believed that it was the responsibility of pediatricians to become involved in community and legislative efforts to prevent childhood drowning; yet, only 4.1% were involved in such efforts. Despite the fact that drowning is a leading cause of injury death in children, only 50.9% of pediatricians gave any anticipatory guidance to children's parents, and only 33.8% gave any guidance to teenagers. In a study of Los Angeles clinicians, only a third stated they counseled families on drowning prevention. Part of the problem is that only 17.9% of pediatricians noted having received formal drowning prevention education during their residency training.

The residential swimming pool should be a focus of preventive efforts because of the

high drowning rate at this site. In one study of pools where children drowned, 75% of pools were inadequately fenced. Only 18% of submersions were witnessed, even though a supervising adult could be identified 84% of the time. Fewer than half of households had any member who knew basic CPR, and 42% of children who died did not receive CPR until paramedics arrived.

Multiple layers of protection are necessary to minimize the risk of pediatric drowning. Education (including basic CPR) in addition to appropriate pool fencing could prevent up to 80% of drowning in young children. Fences should completely isolate the pool from the house and yard (isolation fencing). Isolation fencing is greatly superior to perimeter fencing (three-sided fence that encloses the property and pool) because perimeter fencing allows pool access through the home. Studies indicate that isolated fencing dramatically reduces the risk of drowning. The odds ratio for the risk of drowning or near-drowning in a fenced pool compared with an unfenced pool is 0.27 (95% CI 0.16–0.47). Proper gates are also important and should be self-closing and self-latching, with latches mounted inside and near the top of the fence.

Not all fences are equally effective. The commonly used 4-ft tall, large chain link (2.5-inch mesh) fence can be scaled by 75% of 2-yr olds in an average time of 25.6?sec and by 100% of 4-yr olds in an average 11.5?sec. Obviously, no commonly used barrier is universally insurmountable by young children. However, in one study, the only barrier insurmountable to children age 4 yr and younger was a 5-ft ornamental iron fence (vertical bars 3.25 inches apart; horizontal crossbars 45 inches apart; and no decorative cutouts on the fence). Clever children may still be able to climb any fence using aids such as chairs or boxes, again emphasizing the need for multiple layers of preventative strategies.

Parents need to closely supervise children at every moment during swimming. Toys should be removed from the pool area at the end of swim time. Pool covers should be American Society for Testing Materials approved. However, because pool covers are often cumbersome, they are unlikely to be replaced immediately after swim time and therefore are not likely to be an effective barrier. Lightweight covers should be discouraged, because they do not prevent the child from entering the pool and may obscure visualization of the submerged child. Door alarms and automatically closing and locking doors are untested in efficacy. Swimming pool alarms alone cannot be recommended at this time; in all alarms tested, a significant number of false alarms and failure to alarm were noted.

Infant and toddler swimming programs are popular throughout the United States. Children are not developmentally ready for swimming lessons until they are 4 yr old (AAP recommendations). Aquatic programs for infants and toddlers have not been shown to decrease the risk of drowning, and parents should not feel secure that their child is safe in water or safe from drowning as a consequence of such programs. School-aged children

should be taught to swim but nonetheless prevented from swimming in unsupervised circumstances.

Parents must be made aware that any body of water, no matter how innocuous, poses a drowning risk, especially to children 4 yr of age and younger. Educating parents about the risks of common household fixtures, such as bathtubs, buckets, toilets, and washing machines, should be every pediatrician's task. Parents must be taught to remain with children throughout the entire bath time. Buckets containing water should never be left unattended. Toilet covers and bathroom doors should be closed at all times. Children with epilepsy can enjoy swimming as long as close supervision is maintained; these children should be encouraged to shower in a glass-free cubicle rather than in a bathtub.

A National Transportation Safety Board review found that only 15% of boaters who drowned wore a personal flotation device (PFD). In a study of boaters in the northwest United States, only 25% wore a PFD. Use was highest in children younger than age 5 yr (91%) and lowest in those older than age 14 yr (13%). If no adult on a boat wore a PFD, then only 65% of children wore one; if at least one adult wore a PFD, then 95% of children wore one as well. Intensive community boating education efforts have been shown to substantially increase PFD use. Water safety education for children, teenagers, and parents that encourages PFD use and never swimming alone should be reinforced in the school, community, and physician's office. Teenagers should learn CPR and be counseled about alcohol and drug use, which significantly contribute to submersion and drowning.

Chapter 62 - Burn Injuries

Alia Y. Antoon
Mary K. Donovan

Burns are a leading cause of unintentional death in children, second only to motor vehicle crashes. There has been a decline in the incidence of burn injury requiring medical care over the past decade. This has coincided with an increased focus on burn treatment and prevention, fire and burn prevention education, availability of regional treatment centers, widespread use of smoke detectors, greater regulation of consumer products and occupational safety, and societal changes such as reduced smoking and alcohol abuse.

Epidemiology.

About 1.2 million people in the United States require medical care for burn injuries each year, with 51,000 requiring hospitalization. Thirty to 40 per cent of these patients are younger than 15 yr of age, with an average age of 32 mo. Fires are a major cause of mortality in children, accounting for up to 34% of fatal injuries in those younger than 16 yr. Scald burns account for 85% of total injuries and are most prevalent in children younger than 4 yr of age. Although the incidence of hot water scalding has been reduced by legislation requiring new water heaters to be preset at 120°F, scald injury remains the leading cause of hospitalization for burns. Flame burns account for 13%; the remaining are electrical and chemical burns. Clothing ignition has declined since passage of the Federal Flammable Fabric Act, requiring sleepwear to be flame retardant; however, the Consumer Product Safety Commission voted to relax the existing children's sleepwear flammability standard. Approximately 18% of burns are the result of child abuse, making it important to assess pattern and site of injury and their consistency with history (see Chapter 35). Friction burns from treadmills are also a significant problem. Anoxia and not the actual burn is a major cause of morbidity and mortality in house fires.

Review of the history usually reveals a common pattern: scald burn to the side of face, neck, and arm if liquid is pulled from a table or stove; a pant leg area burn if clothing ignites; splash areas from cooking; and palm of hand contact with a hot stove. However, “glove or stocking” burns of hands and feet, single-area deep burns on the trunk, buttocks, or back, and small-area, full-thickness burns (cigarette burns) in young children should raise the suspicion of child abuse.

Burn care involves a range of activities: prevention, acute care and resuscitation, wound management, pain relief, reconstruction, rehabilitation, and psychosocial adjustment. Children with massive burns require early and appropriate psychologic and social support as well as resuscitation. Surgical débridement, wound closure, and rehabilitative efforts should be instituted concurrently to promote optimal rehabilitation. Aggressive surgical removal of devitalized tissue, infection control, and judicious use of antibiotics as well as early nutrition and cautious use of intubation and mechanical ventilation are necessary to maximize survival. Children who have sustained burn injuries differ in appearance from their peers, necessitating supportive efforts for re-entry to schooling and social and sporting activities.

Prevention.

The aim is a continuing reduction in the number of serious burn injuries (Box 62–1). Effective first aid and triage can decrease both the extent (area) and the severity (depth) of injuries. Flame-retardant clothing, smoke detectors, and control of hot water temperature (thermostat settings) within buildings as well as prohibition of cigarette smoking have been partially successful in reducing the incidence of burn injuries. Dedicated burn unit treatment of children with significant burn injuries facilitates medically effective care, improves survival, and leads to greater cost efficiency. Survival of at least 80% of patients with 90% body surface burns is now usual; overall survival of children with burns of all sizes is 99%. Deaths are more likely in children with irreversible anoxic brain injury sustained at the time of the burn.

Pediatricians can play a major role in preventing the most common burns by educating parents and care providers in preventive measures geared to the various stages of child development. Appropriate clothing, smoke detectors, and planned routes for emergency exit from the home are simple, effective, efficient, and cost-effective preventive measures. Child neglect

Box 62-1. Burn Prophylaxis

PREVENT FIRES

- Smoke detectors
- Control of hot water thermostat–public buildings (maximum water temperature 120° F)
- Learn to use fire-matches-lighter to prevent injury
- Prevent cigarette smoking
- Flame retardant–treated clothing

PREVENT INJURY

- Roll, not run, if clothing catches fire; wrap in blanket
- Practice escape procedures
- Crawl beneath smoke if indoors
- Use of materials for education*

***National Fire Protection Association pamphlets and videos.**

and abuse must be seriously considered when the history of the injury and the distribution of the burn do not match.

Acute Care, Resuscitation, and Assessment

INDICATIONS FOR ADMISSION (Box 62–2).

Burns covering greater than 10–15% of total body surface area (BSA), burns associated with smoke inhalation, burns resulting from high-tension electrical injuries, and burns associated with suspected child abuse or neglect should be treated as emergencies and the child hospitalized. Small first- and second-degree burns of the hands, feet, face, perineum, and joint surfaces also require admission if close follow-up care is difficult to provide. Children who have been in enclosed-space

fires and those who have face and neck burns should be hospitalized for at least 24?hr of observation for signs of central nervous system (CNS) effects of anoxia from carbon monoxide poisoning or pulmonary effects from smoke inhalation.

FIRST AID MEASURES.

Acute care should include the following:

1. Extinguish flames by rolling on the ground; cover the child with a blanket, coat, or carpet.
2. After determining that the airway is patent, remove smoldering clothing or clothing saturated with hot liquid. Jewelry, particularly rings and bracelets, should be removed or cut away to prevent constriction and vascular compromise during the edema phase in the first 24–72?hr post burn.
3. In cases of chemical injury, brush off any remaining chemical if powdered or solid; then use copious irrigation or wash the affected area with water. Call Poison Control for the neutralizing agent to treat a chemical ingestion.
4. Cover the burned area with clean, dry sheeting and apply cold (not iced) wet compresses to small injuries. Significant large burn surface area injury (>15–20% BSA) decreases body temperature control and contraindicates the use of cold compress dressings.
5. If the burn is caused by hot tar, use mineral oil to remove the tar.

Box 62-2. Indications for Hospitalization for Burns

Burns greater than 15% body surface area

High-tension wire electrical burns

Inhalation injury regardless of the size of body surface area burn

Inadequate home situation

Suspected child abuse or neglect

Burns to hands, feet, genitals

EMERGENCY CARE (Box 62–3).

Life support measures should include the following:

1. Rapidly review the cardiovascular and pulmonary status and document pre-existing or physiologic lesions (e.g., asthma, congenital heart disease, renal or hepatic disease).
2. Ensure and maintain an adequate airway and provide humidified oxygen by mask or endotracheal intubation. The latter may be needed in children who have facial burns or a burn sustained in an enclosed space, before facial or laryngeal edema becomes evident. If hypoxia or carbon monoxide poisoning is suspected, 100% oxygen should be used (see Chapters 57.1 and 57.3).
3. Children with burns greater than 15% of BSA require intravenous fluid resuscitation to maintain adequate perfusion. All inhalation injuries, regardless of the extent of BSA burn, require venous access to control fluid intake. All high-tension and electrical injuries require venous access to ensure forced alkaline diuresis in case of muscle injury to avoid myoglobinuric renal damage. Lactated Ringer solution, 10–20?mL/kg/hr (normal saline may be used if lactated Ringer is not available), is infused until proper fluid replacement can be calculated. Consultation with a specialized burn unit should be made to coordinate fluid therapy, type of fluid, preferred formula for calculation, and preferences for use of colloid agents, particularly if transfer to a burn center is anticipated.
4. Evaluate the child for associated injuries, which are common in patients with a history of high-tension electrical burn, especially if there has been a fall from a height. Injuries to spine, bones, and thoracic or intra-abdominal organs may occur (see Chapter 57.8). The child should be placed on cervical spine precaution until this injury is ruled out. There is a very high risk of cardiac abnormalities, including ventricular tachycardia or ventricular fibrillation, resulting from conductivity of the high electric voltage. Cardiopulmonary resuscitation should be instituted promptly at the scene, and the patient should be placed on a cardiac monitor on arrival at the emergency department (see Chapter 57.1).
5. Children with burns greater than 15% BSA should not receive oral fluids (initially), because they may develop ileus. These children require insertion of a nasogastric tube in the emergency department to prevent aspiration.
6. A Foley catheter should be inserted to monitor urine output in all children who require intravenous fluid resuscitation.
7. All wounds should be wrapped with sterile towels until a decision is made about whether to treat on an outpatient basis or refer the patient to an appropriate facility for treatment.

CLASSIFICATION OF BURNS.

Proper triage and treatment of burn injury require assessment of the extent and depth of the injury (Table 62–1). *First-degree burns* involve only the epidermis and are characterized by swelling, erythema, and pain (similar to a mild sunburn). Tissue damage is usually minimal, and there is no blistering. Pain resolves in 48–72?hr; in a small percentage of patients the damaged epithelium will peel off, leaving no residual scars.

A *second-degree burn* involves injury to the entire epidermis and a variable portion of the dermal layer (vesicle and blister formation are characteristic of second-degree burns). A *superficial* second-degree burn is extremely painful because a large

TABLE 62-1 -- **Burn Depth Categories**

	First Degree	Second Degree Partial Thickness	Third Degree Full Thickness
Surface Appearance	Dry, no blisters. Minimal or no edema. Erythematous.	Moist blebs, blisters. Underlying tissue is mottled pink and white with good capillary refill.	Dry, leathery eschar. Mixed white, waxy, khaki, mahogany, soot stained.
Pain	Very painful.	Very painful.	Insensate.
Histologic Depth	Epidermal layers only.	Epidermis, papillary, and reticular layers of dermis. May include domes of subcutaneous layers.	Down to and may include fat, subcutaneous tissue, fascia, muscle, and bone.
Healing Time	2–5 days with no scarring.	Superficial: 5–21 days with no grafting. Deep partial: 21–35 days with no infection. If infected, converts to full thickness.	Large areas require grafting. Small areas may heal from the edges after weeks.

number of remaining viable nerve endings are exposed. Superficial second-degree burns heal in 7–14 days as the epithelium regenerates in the absence of infection. *Midlevel* to *deep* second-degree burns also heal spontaneously if wounds are kept clean and infection free. Pain is less than in more superficial burns, because fewer nerve endings remain viable. Fluid losses and metabolic effects of deep dermal (second-degree) burns are essentially the same as those of third-degree burns.

Full-thickness or *third-degree* burns involve destruction of the entire epidermis and dermis, leaving no residual epidermis cells to repopulate the damaged area. The wound cannot epithelialize and can heal only by wound contraction or skin grafting. The absence of painful sensation and capillary filling demonstrates the loss of nerve and capillary elements.

ESTIMATION OF BODY SURFACE AREA OF BURN.

Appropriate burn charts for different childhood age groups should be used to accurately estimate the extent of BSA burned. The volume of fluid needed in resuscitation is calculated from the estimation of the extent and depth of burn surface. Mortality and morbidity also depend on the extent and depth of the burn. The variable growth rate of the head and extremities throughout childhood makes it necessary to use surface area charts, such as that modified by Lund and Brower or the chart used at the Shriners Hospital in Boston (Fig. 62–1). The “rule of nines” used in adults may be used only in children older than age 14 yr or as a very rough estimate to institute therapy before transfer to a burn center. In small burns under 10% of BSA, the “rule of palm” may be used, especially in outpatient settings. The area from the wrist crease to finger crease (the palm) in the child equals 1% of the child's BSA.

TREATMENT

OUTPATIENT MANAGEMENT OF MINOR BURNS.

First- and second-degree burns less than 10% BSA may be treated on an outpatient basis unless there is inadequate family support or there are issues of child neglect or abuse. These outpatients do not require a tetanus booster or prophylactic penicillin therapy. Children who are not current with immunizations should have their immunizations updated. Blisters should be left intact and dressed with bacitracin or silver sulfadiazine cream (Silvadene). Dressings should be changed once daily, after the wound is washed with lukewarm water to remove any cream left from the previous application. Very small wounds, especially those on the face, may be treated with bacitracin ointment and left open. Débridement of the devitalized skin is indicated when the blisters rupture. Burns to the palm with large blisters usually heal beneath the blisters, with close follow-up on an outpatient basis. The great majority of superficial burns heal in 10–20 days. Deep second-degree burns take longer to heal and may benefit from Polysporin powder placed on the wound and covered with collagenase ointment, which is changed daily. Pain control should be accomplished by using acetaminophen with codeine 1 hour before dressing changes. Wounds that appear deeper than at initial assessment or that have not healed by 21 days may require a short hospital admission for grafting.

The depth of scald injuries is difficult to assess early; conservative treatment is appropriate to allow maturation and declaration of the depth and area involved before closure is attempted. This obviates the risk of anesthesia and unnecessary grafting and diminishes potential scarring in those patients in whom spontaneous healing is likely to occur.

FLUID RESUSCITATION.

For most children the Parkland formula is an appropriate starting guideline for fluid resuscitation (4?mL lactated Ringer/kg/% BSA burned). One half of the fluid is given over the first 8?hr calculated from the time of onset of injury. The remaining half is given at an even rate over the next 16?hr. The rate of infusion is adjusted according to the patient's response to therapy. Pulse and blood pressure should return to normal, and an adequate urine output (1?mL/kg/hr) should be accomplished by varying the intravenous infusion rate. Vital signs, acid-base balance, and mental status reflect the adequacy of the resuscitation. Because of interstitial edema and sequestration of fluid in muscle cells, patients may gain up to 20% over baseline pre-burn body weight. Patients with burns of 30% BSA require a large venous access (central venous line) to deliver the fluid required over the critical first 24?hr. Patients with burns greater than 60% BSA may require a multilumen central venous catheter; these patients are best cared for in a specialized burn unit.

During the second 24?hr after the burn, patients will begin to reabsorb edema fluid and to diurese. One half of the first day's fluid requirement is infused as lactated Ringer solution in 5% dextrose. Children younger than age 5 yr may require the addition of 5% dextrose in the first 24?hr of resuscitation. Controversy exists as to whether colloid should be provided in the early period of burn resuscitation. One preference is to use colloid replacement concurrently if the burn is greater than 85% total BSA. Colloid is usually instituted 8–24?hr after the burn injury. In children younger than 12 mo of age, sodium tolerance is limited; volume and sodium concentration of the resuscitation solution should be decreased if urinary sodium is rising. Adequacy of resuscitation should be constantly assessed using vital signs, blood gases, hematocrit, and protein levels. Some patients require arterial and central venous lines, particularly if undergoing multiple excision and grafting procedures as needed, for monitoring and replacement purposes. Central venous pressure monitoring may be indicated to assess circulation and urine output for patients with hemodynamic or cardiopulmonary instability. Femoral vein cannulation is a safe access for fluid resuscitation especially in infants and children. Burn patients who require frequent blood gas monitoring benefit from radial or femoral arterial catheterization.

Oral supplementation may start as early as 48?hr postburn. Milk formula, artificial feedings, homogenized milk, or soy-based products can be given by bolus or constant infusion through a nasogastric or small bowel feeding tube. As oral fluids

Figure 62-1 Chart to determine developmentally related per cent body burn surface area. (Courtesy of Shriners Hospital for Crippled Children, Burn Institute, Boston Unit.)

are tolerated, intravenous fluids are decreased proportionately in an effort to keep the total fluid intake constant, particularly if pulmonary dysfunction is present.

Five per cent albumin infusions may be used to maintain the serum albumin levels at a desired 2?g/dL. The following rates are effective: for total BSA burns of 30–50%, 0.3?mL of 5% albumin/kg/% BSA burn is infused over a 24-hr period; for total BSA burns of 50–70%, 0.4?mL/kg/% BSA burn is infused over 24?hr; and for total BSA burns of 70–100%, 0.5?mL/kg/% BSA burn is infused over 24?hr. Packed red cell infusion is recommended if the hematocrit falls below 24% (hemoglobin =8?g/dL). Some recommend treating hematocrits below 30% or hemoglobin under 10?g/dL in patients with systemic infections, hemoglobinopathies, cardiopulmonary disease, or anticipated (or ongoing) blood loss when repeated excision and grafting of full-thickness burns is likely to be needed. Fresh frozen plasma is indicated if clinical and laboratory assessment reveals a deficiency of clotting factors, a prothrombin level above 1.5 times control, or a partial thromboplastin time of greater than 1.2 times control in children who are bleeding or are scheduled for an invasive procedure or a grafting procedure that could result in an estimated blood loss of over half the blood volume. Fresh frozen plasma may be used for volume resuscitation within 72?hr of injury in patients younger than 2 yr of age with burns over 20% BSA and associated inhalation injury.

Sodium supplementation may be required for children having burns greater than 20% BSA, if 0.5% silver nitrate solution is used as the topical antibacterial burn dressing. Sodium losses with silver nitrate therapy are regularly as high as 350?mmol sodium/m^2 burn surface area. Oral sodium chloride supplement of 4?g/m^2 burn area per 24?hr is usually well tolerated, divided into four to six equal doses to avoid osmotic diarrhea. The aim is to maintain serum sodium levels over 130?mEq/L and urinary sodium concentration over 30?mEq/L. Intravenous potassium supplementation is supplied to maintain serum potassium level over 3?mEq/dL. Potassium losses may be significantly increased when 0.5% silver nitrate solution is used as the topical antibacterial agent or when aminoglycoside, diuretic, or amphotericin therapy is required.

PREVENTION OF INFECTION AND SURGICAL MANAGEMENT OF THE BURN WOUND.

Controversy exists over the prophylactic use of penicillin for all acute hospitalized burn patients and the periodic replacement of central venous catheters to prevent infection. In some units a 5-day course of penicillin therapy is used for all acute burns; standard-dose crystalline penicillin is given orally or intravenously in four divided doses. Erythromycin may be used as an alternative in penicillin-allergic children. Other units have discontinued prophylactic use of penicillin therapy without an increase in the infection rate. Similarly, there is conflicting evidence as to whether relocation

of the intravenous catheter every 48–72?hr decreases or increases the incidence of catheter-related sepsis. It is recommended that the central venous catheter be replaced and relocated every 7 days, even if the site is not inflamed and there is no suspicion of catheter-related sepsis.

Mortality related to the burn injury is associated not with the toxic effect of thermally injured skin but with the metabolic and bacterial consequences of a large open wound, reduction of the patient's host resistance, and malnutrition. These

abnormalities set the stage for life-threatening bacterial infection originating from the burn wound. Wound treatment and prevention of wound infection also promote early healing and improve aesthetic and functional outcomes. *Topical treatment* of the burn wound using 0.5% silver nitrate solution, silver sulfadiazine cream, or Sulfamylon cream, and the use of combination Polysporin powder and collagenase ointment, aims at prevention of infection (Table 62–2). The latter three agents have tissue-penetrating capacity. Regardless of choice of topical antimicrobial agent, it is essential that all third-degree *burn tissue be fully excised* before bacterial colonization occurs and the area be grafted as early as possible to prevent deep wound sepsis. Children having a BSA burn of over 30% should be housed in a *bacteria-controlled nursing unit* to prevent cross contamination and to provide a temperature- and humidity-controlled environment to minimize hypermetabolism.

Deep second-degree burns greater than 10% BSA benefit from early *excision and grafting*. To improve outcome, sequential excision and grafting of third-degree and deep second-degree burns is required in children with large burns. Prompt excision and immediate wound closure is achieved with autografts, often meshed to increase the efficiency of cover. Alternatives for wound closure, such as allografts, xenografts, and Integra and other synthetic skin cover (bilaminate membrane composed of a porous lattice of cross-linked chondroitin-6-sulfate engineered to induce neovascularization as it is biodegraded), may be important for wound coverage in patients with extensive injury to limit fluid, electrolyte, and protein losses and to reduce pain and minimize temperature loss. Epidermal cultured cells (autologous keratinocytes) are a costly alternative and not always successful. Early staged or total excision can be safely carried out by an experienced burn team while burn fluid resuscitation continues. Important keys to success include (1) accurate preoperative and intraoperative determination of burn depth, (2) the choice of excision area and appropriate timing, (3) control of intraoperative blood loss, (4) specific instrumentation, (5) choice and use of perioperative antibiotics, and (6) type of wound coverage chosen. The above process can accomplish early coverage without the use of growth hormone.

NUTRITIONAL SUPPORT.

Supporting the increased energy requirements of a burn is a high priority. The burn injury produces

TABLE 62-2 -- **Topical Agents for Burns**

Agent	Effectiveness	Ease of Use
Silver sulfadiazine	Broad spectrum	Closed dressings
Silvadene cream	Good penetration	Changed twice daily
		Residue *must* be washed off with each dressing change
Mafenide acetate	Broad spectrum, including *Pseudomonas*	Closed dressings
		Changed twice daily
	Rapid and deep wound penetration	Residue *must* be washed off with each dressing change
0.5% Silver nitrate solution	Bacteriostatic	Closed bulky dressing soaked every 2 hr and changed once a day
	Broad spectrum, including some fungi	
	Superficial penetration	
Polysporin powder	Broad spectrum, enzymatic débridement	Closed dressing; once-a-day change
Cover with collagenase ointment		

a hypermetabolic response characterized by both protein and fat catabolism. Children with a 40% total BSA burn require approximately 50% above predicted basal energy expenditure for their age. Early excision and grafting can decrease the energy requirement. Pain, anxiety, and immobilization increase the physiologic demands. Additional energy expenditure is caused by cold stress if environmental humidity and temperature are not controlled; this is especially true in young infants, in whom the largest surface area:mass ratio allows proportionately greater heat loss than in adolescents and adults. Calorie demands can be decreased by providing environmental temperatures of 28–33°C, adequate covering during transport, and liberal use of analgesics and anxiolytics. Special units to control ambient temperature and humidity may be necessary for children having large surface area burns. Appropriate sleep intervals are necessary and should be part of the regimen.

The objective of caloric supplementation programs is to maintain body weight and meet metabolic demands. This reduces the loss of lean body mass. Calories are provided at one and one half times the basal metabolic rate, 3–4?g/kg of protein per day. Propranolol, in children with more than 40% BSA burns, in sufficient doses to reduce the resting heart rate by 20%, also reduces resting energy expenditure and improves muscle nitrogen balance. Multivitamins, particularly the B vitamin group, vitamin C, vitamin A, and zinc, are also necessary.

Alimentation should be started as soon as is practical, both orally and intravenously, to meet all the caloric needs and keep the gastrointestinal tract active after the resuscitative phase. Patients with greater than 40% total BSA burns need a flexible nasogastric or small bowel feeding tube to facilitate continuous delivery of calories without the risk of aspiration. To decrease the risk of infectious complications, parenteral nutrition is discontinued as soon as is practical after delivery of sufficient enteral calories is established. Continuous gastrointestinal feeding is essential even if feeding is interrupted, owing to frequent visits to the operating room until the full grafting takes place.

TOPICAL THERAPY.

Topical therapy is widely used and is effective against most burn pathogens (see Table 62–2). A number of agents (0.5% silver nitrate, sulfacetamide acetate, silver sulfadiazine cream, and the combination of collagenase ointment and Polysporin

powder) can be used on small second-degree burns. Preferences vary among burn units. Each topical agent has advantages and disadvantages in application, comfort, and bacteriostatic spectrum. Sulfacetamide acetate is a very effective broad-spectrum agent with the ability to diffuse through the burn eschar and is thus the treatment of choice in injury to cartilaginous surfaces, such as ears. The carbonic anhydrase inhibition activity of sulfacetamide may cause acid-base imbalance if large surface areas are treated, and adverse reactions to the sulfur-containing agents may produce a transient leukopenia.

INHALATIONAL INJURY.

This injury is serious in the infant and child, particularly if pre-existing pulmonary conditions are present (see Chapter 57.3). Mortality estimates vary depending on the criteria for diagnosis but are 45–60% in adults; exact figures are not available in children. Evaluation aims at early identification of inhalational airway injuries. These may occur from (1) direct heat (greater problems with steam burns), (2) acute asphyxia, (3) carbon monoxide poisoning, and (4) toxic fumes, including cyanides from combustible plastics. Sulfur and nitrogen oxides and alkalis formed during the combustion of synthetic fabrics produce corrosive chemicals that may erode mucosa and cause significant tissue sloughing. Exposure to smoke may cause degradation of surfactant and decrease its production, resulting in atelectasis. Inhalation injury and burn injury are synergistic, and the combined effect can increase morbidity and mortality.

The pulmonary complications of burns and inhalation can be divided into three syndromes with distinct *clinical manifestations* and temporal patterns:

1. *Early* carbon monoxide poisoning, airway obstruction, and pulmonary edema are major concerns.
2. The acute respiratory distress syndrome usually becomes clinically evident later, at 24–48?hr, although it can occur even later (see Chapter 58).
3. *Late* complications (days to weeks) include pneumonia and pulmonary emboli.

Inhalation injury should be assessed by evidence of obvious injury (swelling or carbonaceous material in nasal passages), wheezing, crackles or poor air entry, and laboratory determination of carboxyhemoglobin (HbCO) and arterial blood gases.

Treatment is initially focused on establishing and maintaining a patent airway through prompt and early nasotracheal intubation and adequate ventilation and oxygenation. Wheezing is common, and ß-agonist aerosols or inhaled corticosteroids are useful. Aggressive pulmonary toilet and chest physiotherapy are necessary in prolonged nasotracheal intubation or in the rare patient with a tracheotomy. The availability of less irritating endotracheal tube materials as well as improved tube and cuff design has allowed progressively longer periods of translaryngeal intubation. An endotracheal tube can be maintained for months without the need for tracheostomy. If tracheotomy has to be performed, it should be delayed until burns at and near the site have healed, and then it should be performed electively with the child under anesthesia and using optimal tracheal positioning and hemostasis. In children with inhalation injury or burns of the face and neck, upper airway obstruction can develop rapidly; endotracheal intubation becomes a lifesaving intervention. All should be aware of the potential damage to the columella when both nasotracheal and nasogastric tubes are used for prolonged periods of time. Extubation should be delayed until the patient meets accepted criteria for maintaining the airway.

Signs of CNS injury from hypoxemia due to asphyxia or carbon monoxide poisoning vary from irritability to depression. Carbon monoxide poisoning may be mild (<20% HbCO), with slight dyspnea and decreased visual acuity and higher cerebral functions; moderate (20–40% HbCO), with irritability, nausea, dimness of vision, impaired judgment, and rapid fatigue; or severe (40–60% HbCO), producing confusion, hallucination, ataxia, collapse, acidosis, and coma. Measurement of HbCO is important for diagnosis and treatment. Pa_{O_2} may be normal and the oxyhemoglobin saturation values misleading because HbCO is not detected by the usual tests of oxygen saturation. Carbon monoxide poisoning is assumed until the tests are performed and is treated with 100% oxygen. Significant CO poisoning requires hyperbaric oxygen therapy (see Chapter 704.10).

Patients with severe inhalation injury or with other causes of respiratory deterioration leading to acute respiratory distress syndrome who fail to improve on conventional pressure controlled ventilation (progressive oxygenation failure as manifested by P_{O_2} below 90% while on F_{IO_2} between 0.9–1.0 and PEEP of at least 12.5?cm H_2O) may benefit from high-frequency ventilation or nitric oxide inhalation treatment. Nitric oxide usually is administered through the ventilator at 5 parts per minute (ppm) and increased up to 30?ppm. This method of therapy reduces the need of extracorporeal membrane oxygenation.

Pain Relief and Psychologic Adjustment (see also Chapter 66).

It is important to provide adequate analgesia, anxiolytics, and psychologic support to reduce early metabolic stress, decrease the potential for post-traumatic stress syndrome (see Chapter 22), and allow future stabilization and rehabilitation. Patients and family require team support to work through a grieving process and accept long-term changes in appearance.

Children having burn injury show frequent and wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn, stage of healing, age and stage of emotional development, cognition, experience and efficiency of the treating team, use of analgesics and other drugs, pain threshold, and interpersonal and cultural factors. From the onset of the treatment, preemptive pain control during dressing changes is of paramount importance. The use of a variety of nonpharmacologic interventions as well as pharmacologic agents needs to be reviewed throughout the treatment period. Opiate analgesia prescribed in an adequate dose and timed to cover dressing changes is essential to comfort management. A supportive person who is consistently present and “knows” the patient profile can integrate and encourage patient participation in burn care. The problem of undermedication is most prevalent with adolescents, in whom fear of drug dependency may inappropriately influence treatment. A related problem is that the child's specific pain experience may be misinterpreted; for example, for anxious patients, those who are confused and alone, or those with pre-existing emotional disorders, even small wounds may illicit intense pain. Anxiolytic medication added to

the analgesic is usually helpful and has more than a synergistic effect. Equal attention is necessary to decrease stress in the intubated patient. Other modalities of pain and anxiety relief (e.g., relaxation techniques) can decrease the physiologic stress response. Oral morphine sulfate (immediate-release) is recommended on a consistent schedule at a dose of 0.3–0.6?mg/kg q4–6h initially and until wound cover is accomplished. Morphine sulfate intravenous bolus at a dose of 0.05–0.1?mg/kg q2h is administered in older patients using a patient-controlled analgesia (PCA) protocol. Morphine sulfate rectal suppositories may be useful at an added dose of 0.3–0.6?mg/kg q4h. For anxiety, lorazepam (Ativan) is given on a consistent schedule, 0.05–0.1?mg/kg/dose q8h. To control pain during a procedure (dressing changes or débridement), oral morphine at a dose of 0.3–0.6?mg/kg is given 1–2?hr before the procedure, and this is supplemented by a morphine intravenous bolus at a dose of 0.05–0.1?mg/kg given immediately before the procedure. Lorazepam at a dose of 0.04?mg/kg is given orally, or intravenously if necessary, for anxiety before the procedure. Midazolam (Versed) is also very useful for conscious sedation given at a dose of 0.05–0.1?mg/kg/hr as an infusion or a bolus; it may be repeated in 10?min, with a maximum dose of 0.2?mg/kg. During the process of weaning from analgesics, the dose of oral opiates is reduced by 25% over 1–3 days, sometimes with the addition of acetaminophen as opiates are tapered. Antianxiety medications are tapered by reducing the dose of benzodiazepines at 25–50% per dose daily over 1–3 days.

For ventilated patients, pain control is accomplished by using morphine sulfate intermittently as an intravenous bolus at a dose of 0.05–0.1?mg/kg q2h. Doses may need to be increased gradually, and some children may need continuous infusion; a starting dose of 0.05?mg/kg/hr given as an infusion is increased

gradually as the need of the child changes. Naloxone is rarely needed but should be immediately available to reverse the effect of morphine, if necessary; if needed for an airway crisis, it should be given in a dose of 0.1?mg/kg up to a total of 2?mg, either intramuscularly or intravenously. For patients on assisted respiration who require treatment of anxiety, midazolam is used as an intermittent intravenous bolus (dose of 0.04?mg/kg given by a slow push q4–6h) or as a continuous infusion. Intubated patients do not require opiates to be discontinued during the process of weaning from the ventilator. Benzodiazepine should be reduced to about half the dose over 24–72?hr before extubation; too rapid weaning from a benzodiazepine can lead to seizures.

Reconstruction and Rehabilitation.

To ensure maximum cosmetic and functional outcome, occupational and physical therapy must begin on the day of admission, continue throughout the hospitalization, and, for some patients, continue after discharge. Physical rehabilitation involves body and limb positioning, splinting, exercises (active and passive movement), assistance with activities of daily living, and gradual ambulation. These measures maintain adequate joint and muscle activity with as normal a range of movement as possible after healing or reconstruction. Pressure therapy is necessary to reduce hypertrophic scar formation; a variety of prefabricated and custom-made garments are available for use in different body areas for prevention of hypertrophic scarring. These custom-made garments deliver consistent pressure on scarred areas; they shorten the time of scar maturation and decrease the thickness of the scar as well as the redness and associated itching. Continued adjustments to scarred areas (scar release, grafting, rearrangement) and multiple minor cosmetic surgical procedures are necessary to optimize long-term function and to improve appearance. Replacement of areas of alopecia and scarring has been achieved using tissue expander techniques.

SCHOOL RE-ENTRY AND LONG-TERM OUTCOME.

It is best for the child to return to school immediately after discharge. Occasionally, a child may need to attend a few half days (because of rehabilitation needs). However, it is important for the child to return to his or her normal routine of attending school and being with peers. Planning for return to home and school often requires a school re-entry program that is individualized to each child's needs. For a school-aged child, planning for the return to school occurs simultaneously with planning for discharge. The hospital schoolteacher contacts the local school and plans the program with school faculty, nurses, social workers, recreational/child life therapists, and rehabilitation therapists. This team should work with students and staff to ease anxiety, answer questions, and provide information. Burns and scars evoke fears in those who are not familiar with this type of injury and can result in a tendency to withdraw from or reject the burned child. A school re-entry program should be appropriate to a child's development and changing educational needs.

Major advances have made it possible to save lives of children with massive burns; whereas some children have had lingering physical difficulties, most have a satisfactory quality of life. The comprehensive burn care that includes experienced multidisciplinary aftercare plays an important role in recovery.

Special Situations

ELECTRICAL BURNS.

There are three types of electrical burns. *Minor electrical burns* usually occur as a result of biting on an extension cord. These injuries produce localized burns to the mouth, which usually involve the upper and lower lip that come in contact with the extension cord. The injury may involve or spare the corners of the mouth. Because these are nonconductive injuries (do not extend beyond the site of injury), hospital admission is not necessary and care is focused on the area of the injury visible in the mouth. Treatment with topical antibiotic creams is sufficient until the patient is seen in a burn unit outpatient department or by a plastic surgeon.

A more serious category of electrical burn is the *high-tension electrical wire burn*, for which children need to be admitted for observation regardless of the extent of the surface area burn. Deep muscle injury is usual and cannot be readily assessed initially. These injuries result from high voltage (>1,000?V) and occur particularly at high-voltage installations, such as electric power stations or railroads; youngsters climb an electric pole and touch an electric box in curiosity or accidentally touch the high-tension electric wire. Such injuries have a mortality rate of 3–15% for children who arrive at the hospital for treatment. Survivors have a high rate of morbidity,

including major limb amputations. Points of entry of current through the skin and the exit site show characteristic features consistent with current density and heat. The majority of entrance wounds involve the upper extremity, with small exit wounds in the lower extremity. The electrical path from entrance to exit takes the shortest distance between the two points and may produce injury in any organ or tissue in the path of the current. Multiple exit wounds in some patients attest to the possibility of several electrical pathways in the body, placing virtually any structure in the body at risk (Table 62–3). Damage to abdominal viscera, thoracic structures, and the nervous system in areas remote from obvious extremity injury occurs and must be sought, particularly in multiple current pathway injury or injury in which the victim falls from a high pole. Sometimes arcing occurs and results in a concurrent flame burn and clothing fire. Cardiac abnormalities manifested by ventricular fibrillation or cardiac arrest are common; patients with high-tension electrical injury need cardiac monitoring until they are stable and have been fully assessed. Renal damage from deep muscle necrosis and subsequent myoglobinuria is another complication; such patients need a forced alkaline diuresis to minimize renal damage. Aggressive removal of all dead and devitalized tissue, even with risk of functional loss, remains the key to effective management of the electrically damaged extremity. Early débridement will facilitate early closure of the wound. Damaged major vessels must be isolated and buried in a viable muscle to prevent exposure. Survival depends on the immediate intensive care, whereas a functional result depends on long-term care and delayed reconstructive surgery.

Lightning burns occur when high-voltage current directly strikes a person (most dangerous) or when the current strikes the ground or an adjacent (in-contact) object. A step voltage burn is observed when lightning strikes the ground and travels up one leg and down the other leg (the path of least resistance). Lightning burns are dependent on the current path, the type of clothing, the presence of metal, and cutaneous moisture. Entry, exit, and path lesions are possible; the prognosis is poorest for lesions of the head or legs. Internal organ injury along the path is common and does not relate to the severity of the cutaneous burn. Linear burns are in the locations where sweat is present and are usually first or second degree. Feathering or an arborescent pattern is characteristic of lightning injury. Lightning may ignite clothing or produce serious cutaneous burns from heated metal in the clothing. Internal complications of lightning burns include cardiac arrest caused by asystole, transient hypertension, premature ventricular contractions, ventricular fibrillation, and myocardial ischemia. Most severe cardiac complications resolve if the patient is supported with cardiopulmonary resuscitation (see Chapter 57.1). CNS complications include cerebral edema, hemorrhage, seizures, mood changes, depression, and lower extremity paralysis. Rhabdomyolysis and myoglobinuria (with possible renal failure) also occur.

RENAL FAILURE IN BURN INJURY (also see Chapters 57.5 and 525).

Renal failure in burn injury is best classified in relation to the time of onset after the burn injury. Most cases present as a nonoliguric renal failure; careful fluid and electrolyte

TABLE 62-3 -- Electrical Injury: Clinical Considerations

	Clinical Manifestations	Management
General		Extrication; ABCs of resuscitation; immobilize spine History: voltage, type of current CBC with platelets, electrolytes, BUN, creatinine, glucose
Cardiac	Dysrhythmias: asystole, ventricular fibrillation, sinus tachycardia, sinus bradycardia, PVC, PAC, conduction defects, atrial fibrillation, ST-T wave changes	Treat dysrhythmias Cardiac monitor, ECG, and chest x-ray film with suspected thoracic injury CPK with isoenzymes if indicated
Pulmonary	Respiratory arrest, acute respiratory distress, aspiration syndrome	Protect and maintain airway Mechanical ventilation if indicated, chest x-ray film, ABG level
Renal	Acute renal failure, myoglobinuria	Aggressive fluid management unless CNS injury Maintain adequate urine output > 1?mL/kg/hr Consider CVP or pulmonary artery pressure monitoring Urine myoglobin, urinalysis, BUN, creatinine
Neurologic	Immediate: loss of consciousness, motor paralysis, visual disturbances, amnesia, agitation; intracranial hematoma Secondary: pain, paraplegia, brachial plexus injury, SIADH, autonomic disturbances, cerebral edema Delayed: paralysis, seizures, headache, peripheral neuropathy	Treat seizures Fluid restriction if indicated Consider spine x-ray films, especially cervical CT scan of brain if indicated
Cutaneous/oral	Oral commissure burns, tongue and dental injuries; skin burns resulting from ignition of clothes, entrance and exit burns, and arc burns	Search for entrance/exit wound Treat cutaneous burns; tetanus status Plastic surgery or ENT consult if needed

Abdominal	Viscus perforation and solid organ damage; ileus; abdominal injury rare without visible abdominal burns	NG tube if airway compromise or ileus SGOT, SGPT, amylase, BUN, creatinine, CT radiographs as indicated
Musculoskeletal	Compartment syndrome from subcutaneous necrosis limb edema and deep burns Long bone fractures, spine injuries	Follow for compartment syndrome X-ray films and orthopedic/general surgery consultations as indicated
Ocular	Visual changes, optic neuritis, cataracts, extraocular muscle paresis	Ophthalmology consultation as indicated

ABC, Airway, breathing, circulation; CBC, complete blood cell count; BUN, blood urea nitrogen; PVC, premature ventricular contractions; PAC, premature atrial contractions; ECG, electrocardiogram; CPK, creatinine phosphokinase; ABG, arterial blood gas; CNS, central nervous system; CVP, central venous pressure; CT, computed tomography; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; ENT, ear, nose, and throat; NG, nasogastric; SGOT, serum glutamate oxaloacetate transaminase (aspartate aminotransferase); SGPT, serum glutamate pyruvate transaminase (alanine aminotransferase).

From Hall ML, Sills RM: Electrical and lightning injuries. In Barkin RM (editor): Pediatric Emergency Medicine. St. Louis, CV Mosby, 1997, p 484.

monitoring are critical. Special considerations of renal failure in a child with burn injury include the initial phase of capillary leak, making resuscitation difficult; severe catabolic stress with increased risk of hyperkalemia; and rapid development of azotemia. Such children require high caloric and protein intake to prevent catabolic stress and promote wound healing.

Renal failure may occur early or late, after 1–3 wk. *Early* renal failure may occur immediately post burn if late resuscitation with subsequent hypovolemia occurs (acute tubular necrosis) or if severe pigment nephropathy (hemoglobinuria with burn injury in an enclosed space or myoglobinuria secondary to deep muscle injury or post escharotomy) develops. This is associated with early maximal catabolic stress, and frequently dialysis is necessary to sustain the circulation in the presence of marked capillary leak and to provide sufficient calories and protein to minimize the catabolic stress. *Late* renal failure may result from sepsis or drug toxicity. At this time there is less catabolic stress, and standard indications for dialysis apply.

Chapter 63 - Cold Injuries

Alia Y. Antoon
Mary K. Donovan

The involvement of children and youth in snowmobiling, mountain climbing, winter hiking, and skiing places them at risk for cold injury. Cold injury may produce either local tissue damage, with the injury pattern depending on exposure to damp cold (frostnip, immersion foot, or trench foot); dry cold (which leads to local frostbite); or generalized systemic effects (hypothermia).

Pathophysiology.

Ice crystals may form between or within cells, interfering with the sodium pump and lead to rupture of cell membranes. Further damage may result from clumping of red blood cells or platelets, causing microembolism or thrombosis. Blood may be shunted away from an affected area by secondary neurovascular responses to the cold injury; this shunting often further damages an injured part while improving perfusion of other tissues. The spectrum of injury ranges from mild to severe and reflects the result of structural and functional disturbance in small blood vessels, nerves, and skin.

Etiology.

In general, body heat may be lost by conduction (wet clothing, contact with metal or other solid conducting objects), convection (wind chill), evaporation, and radiation. Susceptibility to cold injury may be increased by dehydration, alcohol or drug use, substance abuse, impaired consciousness, exhaustion, hunger, anemia, impaired circulation due to cardiovascular disease, and sepsis, as well as in very young or aged persons.

Hypothermia occurs when the body can no longer sustain normal core temperature by physiologic mechanisms such as vasoconstriction, shivering, muscle contraction, and nonshivering thermogenesis. When shivering ceases, the body is unable to maintain its core temperature; when the body core temperature falls below 35°C, the syndrome of hypothermia occurs. Wind chill, wet or inadequate clothing, or other

factors increase local injury and may cause dangerous hypothermia, even in the presence of an ambient temperature that is not lower than 17–20℃ (50–60℉).

Clinical Manifestations

FROSTNIP.

This results in the presence of firm, cold white areas on the face, ears, or extremities. Blistering and peeling may occur over the next 24–72?hr, occasionally leaving mild increased hypersensitivity to cold for some days or weeks. Treatment consists of warming the area with an unaffected hand or warm object before the lesion reaches a stage of stinging or aching and before numbness supervenes.

IMMERSION FOOT (TRENCH FOOT).

This occurs in cold weather when the feet remain in damp or wet, poorly ventilated boots. The feet become cold, numb, pale, edematous, and clammy. Tissue maceration and infection are likely, and prolonged autonomic disturbance is common. This autonomic disturbance leads to increased sweating, pain, and hypersensitivity to temperature changes, which may persist for years. The treatment is largely prophylactic and consists of using well-fitting, insulated, waterproof, nonconstricting footwear. Once damage has occurred, patients must choose clothing and footwear that are more appropriate, dry, and well fitting. The disturbance in skin integrity is managed by keeping the affected area dry and well ventilated and preventing or treating infection. Only supportive measures are possible for control of autonomic symptoms.

FROSTBITE.

With frostbite, initial stinging or aching of the skin progresses to cold, hard, white anesthetic and numb areas. On rewarming, the area becomes blotchy, itchy, and often red, swollen, and painful. The injury spectrum ranges from complete normality to extensive tissue damage, even gangrene, if early relief is not obtained.

Treatment consists of warming the damaged area. It is important not to cause further damage by attempting to rub the area with ice or snow; initial warming as in frostnip may be tried. The area may be warmed against an unaffected hand, abdomen, or axilla while in transfer to a facility where more rapid warming with a water bath is possible. If the skin becomes painful and swelling occurs, anti-inflammatory agents are helpful, and an analgesic agent is necessary. Freeze and re-thaw cycles are most likely to cause permanent tissue injury, and it may be necessary to delay definitive warming and apply only mild measures if the patient is required to walk on the damaged feet en route to definitive treatment. In the hospital, the affected area should be immersed in warm water (temperature approximately 42℃), being careful not to burn the anesthetized skin. Vasodilating agents, such as prazosin or phenoxybenzamine, may be helpful. Anticoagulants (heparin, dextran) have provided equivocal results; results of chemical and surgical sympathectomy have also been equivocal. Oxygen is of help only at high altitudes. Meticulous local care, prevention of infection, and keeping the rewarmed area dry, open, and sterile provide optimal results. Recovery can be complete, and prolonged observation with conservative therapy is justified before any excision or amputation of tissue is considered.

Analgesia and maintenance of good nutrition are necessary throughout the prolonged waiting period.

HYPOTHERMIA.

Hypothermia may occur in winter sports when injury, equipment failure, or exhaustion decreases the degree of exertion, particularly if sufficient attention is not paid to wind chill. Immersion in frozen bodies of water and wet wind chill rapidly produce hypothermia. As the core temperature of the body falls, an insidious onset of extreme lethargy, fatigue, incoordination, and apathy follows, followed by mental confusion, clumsiness, irritability, hallucinations, and finally bradycardia. A number of medical conditions, such as cardiac disease, diabetes mellitus, hypoglycemia, sepsis, ß-blocking agent overdose, and substance abuse, may need to be considered in a differential diagnosis. The decrease in rectal temperature to less than 34℃ (93℉) is the most helpful diagnostic feature. Hypothermia associated with near-drowning is discussed in Chapter 61 .

Prevention is a high priority. Of extreme importance for those who participate in winter sports is wearing layers of warm clothing, gloves, socks within insulated boots that do not impede circulation, and a warm head covering, as well as applying adequate waterproofing and protecting against the wind. Thirty per cent of heat loss occurs from the head. Ample food and fluid need to be provided during exercise. Those who participate in sports should be alert to the presence of cold or numbing of body parts, particularly the nose, ears, and extremities, and they should review methods to produce local warming and know to seek shelter if they detect symptoms of local cold injury. Application of petrolatum (Vaseline) to nose and ears give certain protection against frostbite.

Treatment at the scene aims at prevention of further heat loss and early transport to adequate shelter. Dry clothing should be provided as soon as practical, and transport should be undertaken if the victim has a pulse. If no pulse is detected at the initial review, cardiopulmonary resuscitation is indicated (see Chapters 57.1 and 61 ; Fig. 63–1). During transfer, jarring and sudden motion should be avoided, because these may cause ventricular arrhythmia. It is often difficult to attain a normal sinus rhythm during hypothermia.

If the patient is conscious, mild muscle activity should be encouraged and a warm drink offered. If the patient is unconscious, external warming should be initially undertaken using

Figure 63-1 Hypothermia treatment algorithm. VF = ventricular fibrillation; VT = ventricular tachycardia. (From American Heart Association: ECC guidelines. Part 8: Advanced challenges in resuscitation. Section 3: Special challenges in ECC. *Circulation* 2002;102:1229.)

blankets and a sleeping bag, often with snuggling with a warm companion to increase the efficiency of warming. On arrival at a treatment center, inhalation of warm, moist air or oxygen, heating pads, or thermal blankets should be used while a

warming bath of 45–48°C (113–118°F) is prepared. Monitoring of serum chemistry values and an electrocardiogram are necessary until the core temperature rises above 35°C and can be stabilized. Control of fluid, pH, blood pressure, and oxygen all are necessary in the early phases of the warming period and resuscitation. In severe hypothermia there may be a combined respiratory and metabolic acidosis. Hypothermia may falsely elevate pH; nonetheless most recommend warming the arterial blood gas specimen to 37°C before analysis and considering the result as in a normothermic patient. In patients with marked abnormalities, warming measures such as gastric or colonic irrigation with warm saline or peritoneal dialysis may be considered, but the effectiveness of these measures to treat hypothermia is unknown. In accidental deep hypothermia (core temperature 28°C) with circulatory arrest, rewarming with cardiopulmonary bypass may be lifesaving for previously healthy young individuals.

CHILBLAIN (PERNIO).

Chilblain (pernio) is a form of cold injury in which erythematous, vesicular, or ulcerative lesions occur. The lesions are presumed to be of a vascular or vasoconstrictive origin. They are often itchy and may be painful and result in swelling and scabbing. The lesions are most often found at the ears, tips of fingers, and toes and on exposed areas of the

legs. The lesions last for 1–2 wk but may persist longer. *Treatment* consists of prophylaxis—avoiding prolonged chilling and protecting potentially susceptible areas with a cap, gloves, and stockings. Prazosin and phenoxybenzamine may be helpful in improving circulation if this is a recurrent problem. For significant itching, local corticosteroid preparations may be helpful.

COLD-INDUCED FAT NECROSIS (PANNICULITIS).

This common, usually benign injury occurs on exposure to cold air, snow, or ice and is manifested in exposed (or, less often, covered) surfaces as red (or, less often, purple to blue) macular, papular, or nodular lesions. *Treatment* is with nonsteroidal anti-inflammatory agents. The lesions may last 10 days to 3 wk. (See Chapter 650 .)

Chapter 64 - Withdrawal or Withholding of Life Support, Brain Death, and Organ Procurement

Lorry R. Frankel
Lawrence H. Mathers

The goal of treatment of children with a life-threatening illness is survival with minimal residual injury or cure. When a physician realizes that further treatment is futile in not preventing death and perhaps harmful to a patient, the family should be compassionately informed. It is very important to determine that further treatment will not avoid death and that it may even prolong the dying process. Decisions about such futility should be based on mutual understanding about the prognosis for living, quality of life, and human dignity. The practices of a pediatric intensive care unit (PICU) with patients and families facing these tragic circumstances should be consistent and reflect the most up-to-date knowledge about a disease, its care, and its prognosis (see Chapter 54). If a patient fulfills brain death criteria, compassionate medical care should continue during efforts to remove the dead patient from life support.

Withholding and Withdrawing of Life Support.

Two basically different groups of patients die in a PICU: (1) previously healthy children who have recently experienced a catastrophic event (motor vehicle injury, near-drowning, or a serious infection); and (2) children with a severe chronic illness that has become terminal (cystic fibrosis, severe inborn errors of metabolism, major congenital malformations). For these latter children and their families, it may be possible to provide appropriate terminal care in a more comfortable setting than the hospital, such as the home or hospice (see Chapter 38).

The decision to provide palliative care needs to involve the primary and critical care physicians, the child (when appropriate), and parents, social services, and clergy (if appropriate) to come to an understanding that further intervention will not improve the outcome. The management of a dying patient should include consideration of resuscitation measures ("code status"), comfort care, and symptom management (pain, nausea, anxiety, dyspnea). In the majority of cases involving children, families and physicians reach an agreement about limitation of care without involvement of the legal system or ethics committees.

Although not fulfilling the criteria of death, some children may have a very limited quality of continuing life. The most severe form of perpetual debilitation is the *persistent vegetative state* (PVS). This is a state of perpetual unconsciousness in which there may be neurologic responsiveness to some external stimuli. PVS exists when there has been lack of neurologic recovery for at least 6 mo, with preservation of only the autonomic nervous system, resulting in the maintenance of vital signs (heart rate, blood pressure, respirations, and temperature). Such patients may require significant nursing care, including feeding (usually via gastrostomy), bathing, assistance with bowel and bladder function, skin care to prevent pressure ulcers (bed sores), airway access via a tracheotomy, and passive range of motion exercises to minimize joint contractures. These children may be cared for at home or in long-term care nursing facilities. Patients in PVS are susceptible to infections, and death usually occurs as a result of pneumonia, urinary tract infection, or complications of a skin lesion. After months or years of caring for a child in PVS, a family may decide to limit various treatment modalities after careful consideration of the risks and benefits of further interventions for the child. These children may have neocortical but not whole brain death as the brainstem continues to function. Legally they are not brain dead and thus are not dead.

Withdrawal of support represents cessation of medical treatment and support already being provided to patients. This should be the standard in brain dead children. It must be made very clear to a family that as life support is withdrawn from a child who is not brain dead but is dependent on this treatment, the outcome is most likely to be death. In practice, withdrawing therapy or care that has already been instituted is more difficult than making the decision not to institute a therapeutic intervention. However, in either case, the decision not to provide a certain level of care is made in the context in which provision of such care would only prolong an inevitable death, perhaps involving additional pain and suffering. Legally there is no difference between not initiating a therapy (withholding) or withdrawing a therapy. Although there is little moral distinction between the provision of ventilator support (and other highly technical forms of care) and the provision of artificial hydration and nutrition to critically ill patients, most clinicians find it more difficult to advocate withdrawal of the latter than to recommend withdrawing mechanical ventilation or inotropic drugs.

One of the most frightening possibilities is represented by the "locked-in-syndrome," wherein outward signs of responsiveness are lacking, owing to paralysis, muscular dysfunction, or acute neurologic insult, but where consciousness persists, unbeknownst to the observers. This syndrome can occur with injuries to the lower brainstem, sparing the neocortex, and should be suspected and ruled out before any definitive pronouncement of neurologic unresponsiveness is made, especially if this diagnosis likely will lead to withdrawal of support and death of the patient.

Brain Death.

Criteria to determine brain death for adult and pediatric patients have been established and are accepted by most states (Table 64–1). Death is defined as irreversible cessation of circulatory and respiratory functions or irreversible cessation of all functions of the entire brain, including the brainstem. Guidelines for assessing brain death in children of different ages also have been established; premature or newborn infants require a longer period of observation than older children or adults (

Box 64–1).

The diagnosis of brain death is established once the cause of the coma is determined and the possibility of recovery of any

TABLE 64-1 -- Diagnosis of Brain Death

Brain Death Criteria	Evaluated by
Prerequisites	History, clinical examination, laboratory, technical investigations
1. A recognized cause of coma, sufficient to explain the irreversible cessationof all brain function 2. Potentially reversible causes of coma must be excluded: a. Sedatives and neuromuscular blocking drugs b. Hypothermia c. Metabolic and endocrine disturbances: Severe electrolyte disturbances Severe hypo- or hyperglycemia d. Uncontrolled hypotension e. Surgically remediable intracranial conditions f. Any other sign that suggests a potentially reversible cause of coma	
Clinical Evaluation	
1. Absence of higher brain function	Lack of consciousness, voluntary movement or responsiveness except for spinal reflexes (stimuli applied to any body region may not elicit motor response within cranial nerve distribution); preferably test in a cranial (trigeminal) dermatome rather than a spinal dermatome; no decorticate or decerebrate posturing, no convulsions
2. Absence of brainstem function	
a. Absence of sympathetic and parasympathetic regulation of the pupils	Pupils in midposition or dilated showing neither direct nor indirect reaction to light
b. Disruption of the pathways controlling eye movement in the brainstem	Absence of spontaneous eye movement, absence of reaction to injection of iced water into the ear (vestibulo-ocular reflex), absence of doll's eye phenomenon (oculocephalic reflexes)
c. Disruption of afferent trigeminal and efferent facial nerve pathways	Absence of blink response to (careful) corneal stimulation
d. Disruption of the afferent and efferent pathways of cranial nerves IX and X in the medulla oblongata	Absence of gag response to stimulation of posterior pharynx, absence of cough on suctioning of the trachea
e. Absence of vagal efferent activity	No significant increase of heart rate on administration of intravenous atropine or on pressure applied to the eyeballs (oculocardiac reflex)
f. Disruption of respiratory control centers of the medulla oblongata	No respiratory movement (as assessed by observation ± capnography) at a $PaCO_2$ above a set limit during a standardized apnea testing
"Confirmatory" Tests	
1. Confirmation of absence of higher brain function	Electrocerebral silence on EEG during at least 30?min
2. Confirmation of complete infarction of the brain and brainstem by confirmation of absence of blood flow	Four-vessel contrast angiography or radionuclide imaging
Observation	
Confirmation of irreversibility	Observation during a set time, ± repeat formal physical examination and confirmatory tests

From Lutz-Dettinger N, de Jaeger A, Kerremans I: Care of the potential pediatric organ donor. Pediatr Clin North Am 2001;48:715–49.

brain function is eliminated. Brain death results from permanent cessation of all brain function in the absence of any factor or agent that could cloud accurate assessment of brain function. Physical examinations by two physicians must demonstrate loss of brainstem responses and include an apnea test, in which the patient is hyperoxygenated and then removed from the ventilator or placed on continuous positive airway pressure. The Pa_{CO_2} is allowed to rise to a level of 60?mm Hg or greater

Box 64-1. Age-Specific Criteria for Brain Death[*]

Children 1 wk–2 mo of age: fulfillment of the clinical criteria listed in Table 64–1 in two separate examinations at least 48?hr apart, or one clinical examination followed by an isoelectric EEG at least 48?hr later

Children 2 mo–1 yr: fulfillment of the clinical criteria described in Table 64–1 in two separate examinations, at least 24?hr apart, or one clinical examination followed by an isoelectric EEG or negative results of a cerebral blood flow study at least 24?hr later

Children > 1 yr: fulfillment of the clinical criteria described in Table 64–1 in two separate examinations at least 12?hr apart

EEG = electroencephalogram.

[*] Criteria for brain death in infants younger than 1 wk of age have not been delineated but should be at least as stringent as for those 1 wk–2 mo of age. It is often very difficult to diagnose brain death in premature infants; the wait period should be at least 72?hr. The standard wait period for adults is 6?hr. Some believe the wait period may be shortened if confirmatory testing is employed. Once brain death is determined, that is the medical time of death.

(usually > 10?min) while appropriate oxygenation is maintained. Laboratory tests also are required to establish the cause of the coma and to preclude toxic, metabolic, paralytic, or sedative causes. Electroencephalograms (demonstrating electrical cerebral silence), cerebral perfusion studies (demonstrating absent four-vessel blood flow to the whole brain by contrast angiography), and intracranial pressure monitoring may be helpful in convincing the parents that their child is brain dead and in facilitating the opportunities for organ donation or discontinuation of life support. Additional ancillary tests include radionuclide angiography, Doppler ultrasonography, brainstem evoked potentials, and xenon CT scans. If the prerequisites in Table 64–1 are fulfilled, no confirmatory tests are legally needed.

Brain death is equivalent to cardiorespiratory death, and a child should be considered legally dead at the time brain death criteria are fulfilled. This determination is crucial to the process of organ procurement that requires harvesting heart, lung, liver, or bowel from a donor whose heart is beating. Despite increasing acceptance of organ donation in the United States, fewer than 20% of eligible donors become organ donors. This results in the death of several thousand potential organ recipients each year while awaiting transplantation.

Organ Procurement

(see Chapter 60). In the United States there are more than 250 hospitals offering solid organ transplants and at least 75 regional organizations that monitor organ availability and try to match donors with available organs. Every major metropolitan center has its own such organization or network. The number of pediatric transplant centers is considerably

smaller. If questions arise about organ transplantation, a 24-hr telephone hotline is maintained at 1-800-355-7427.

When the diagnosis of brain death has been made and the family wishes to pursue organ donation, a transplant donor network should be contacted to assist in the process. A procurement coordinator generally assumes responsibility for the donation process, including family discussions, determining arrangements and logistics, obtaining consent forms, making arrangements for appropriate laboratory tests, contacting various transplant centers to make arrangements for organ retrieval, and checking on recipient lists to match the organs to the patient with the highest priority. The coordinator is able to provide the donor's family long-term follow-up about organ placement; many grieving families find this to be very helpful in dealing with their loss. Most donor organizations assume full financial responsibility for the procurement process and the donated organs.

Chapter 65 - Anesthesia and Perioperative Care

Randall C. Wetzel

The perioperative period is a particularly dangerous time for infants and children. Potent drugs are used to blunt physiologic responses to what would be otherwise life-threatening trauma (e.g., surgery). Anesthesia is necessary on humane grounds. In addition, the appropriate application of anesthetic principles decreases mortality from surgery and painful procedures and enhances the child's ability to survive the surgical experience. Intraoperatively, the anesthesiologist is responsible for providing analgesia as well as physiologic and metabolic stability (Box 65–1). These goals are facilitated by a good preanesthesia history (Box 65–2). The increased risk for morbidity and mortality in the perioperative period demands the utmost vigilance. The risk may be increased in certain disease states (Table 65–1). The primary purpose of general anesthesia is to suppress the conscious perception of, and physiologic response to, noxious stimuli and to render the patient unconscious.

GENERAL ANESTHESIA

Analgesia

Providing analgesia perioperatively, and for procedures, is a major responsibility and functions within a spectrum of care (Box 65–3). Techniques exist to provide profound pain relief during operative procedures for even the most critically ill

Box 65-1. The Goals of Anesthesia

1. Analgesia
2. Amnesia and decreased level of consciousness
3. Akinesia
4. Physiologic support and homeostatic management throughout the perioperative process
5. Vigilance

infants. Blunting the physiologic responses to painful stimuli inhibits the stress response and its multiple deleterious physiologic and metabolic consequences. The response to painful and stressful stimuli is a potent stimulus of the systemic inflammatory response syndrome (SIRS), which leads to increased catabolism, physiologic instability, and increased mortality. However, appropriate medication use, such as fentanyl anesthesia in neonates, reduces the incidence of postoperative bradycardia, hypotension, acidosis, and hypoglycemia.

Hypnosis and Amnesia

The blunting of consciousness (hypnosis) and conscious recall (amnesia) are crucial aspects of pediatric anesthesia care. Awareness of painful, anxiety-provoking, and stressful conditions for children is just as deleterious, physically and psychologically, as the painful procedures themselves. Management is aimed at blunting the fear and emotional response that surgery, painful procedures (bone marrow aspiration, lumbar punctures), and nonpainful but anxiety-provoking procedures (MRI, CT scans) can invoke. There are many drugs that provide anxiolysis, blunting of recall, and amnesia for such events (Table 65–2). Obtundation of consciousness may accompany the provision of analgesia. Altered consciousness can be induced by hypnotic and sedative agents without producing any analgesia; analgesia and obtunded consciousness are not synonymous. It is also possible to provide analgesia (local analgesia, spinal or epidural analgesia) without obtunding consciousness.

Sedation describes a medically induced state, which is a continuum between awake and general anesthesia (see Box 65–3). General anesthesia obtunds or ablates critical physiologic reflexes; the most important are airway protective reflexes: coughing, gagging, and swallowing. Cardiorespiratory reflexes are also obtunded with general anesthesia, and thus respiratory depression and hemodynamic compromise may occur. As sedation deepens toward general anesthesia, the loss of airway patency, the loss of airway protective reflexes, and the loss of cardiovascular stability occur. Light (minimal) sedation is anxiolysis without loss of these reflexes and airway patency. Deep sedation is when these reflexes are obtunded or lost (see Box 65–3). Adequate sedation in children may be accompanied by the actual or potential loss of vital reflexes. It is mandatory that those providing sedation for children be able to detect the transition into deep sedation and general anesthesia and be prepared to manage the child's airway and provide cardiorespiratory resuscitation if required.

Akinesia

Akinesia is the absence of movement and is necessary to ensure safe and adequate operative conditions and to provide ideal conditions for advanced and meticulous surgery. Akinesia is produced with muscle relaxants (see Table 65–2). These agents facilitate respiratory management in the perioperative period and in critically ill patients. The absence of movement is neither the absence of pain nor the presence of amnesia. Whenever

neuromuscular blocking agents are used, analgesia and sedation should be provided.

Physiologic Support

The need for anesthesia increases the need to monitor and support physiologic integrity and homeostasis. Sedation and anesthesia have significant and potentially life-threatening physiologic consequences (see Table 65–2 and Box 65–3). The maintenance of adequate cardiorespiratory function, fluid management, electrolyte control, thermoregulation, and concern for all aspects of the child's health is critical during anesthesia.

Vigilance

Constant, critical attention by physicians who understand the changes in physiologic status and their implications is mandatory to provide safe perioperative care for all children. Careful attention to the child's preoperative condition is mandatory in minimizing the risk in perioperative care (see Box 65–2 and Table 65–1).

INDUCTION OF GENERAL ANESTHESIA

The goal of induction of general anesthesia is to rapidly achieve surgical anesthesia by using intravenous or, more commonly in children, inhalational induction agents. It is routine in children who are too young to tolerate establishing vascular access before the induction of anesthesia to induce anesthesia by inhalation of volatile anesthetics. In the operating room, a child is often accompanied by parents and placed on the operating room table. Before induction of anesthesia, monitors are placed on the child. These include a pulse oximeter, electrocardiogram (ECG) electrodes, and frequently a blood pressure cuff. The child is then cautiously introduced to the face mask, which contains a high gas flow, 5–7?L/min of oxygen, frequently mixed with nitrous oxide. Sixty to 90?sec of inhalation of nitrous oxide and oxygen induces a state of euphoria. The airway responses to inhalational anesthetics are now blunted, and sevoflurane or halothane can be introduced into the inhaled gas mixture. This leads to unconsciousness within 30–60?sec while the child continues to breathe spontaneously.

The child is now "asleep," and the parents can be asked to leave. An intravenous line is then started and comprehensive intraoperative monitoring initiated. Surgical anesthesia can be maintained by spontaneous ventilation with a mask; however, this is safe when the airway is secure and patent, the stomach is empty, and the child is older than 6 mo of age. Procedures over 1?hr are not usually performed with mask inhalational anesthesia. If these conditions are not met or if the surgeon needs to approach the airway (otolaryngologic procedures), securing the airway with an endotracheal intubation is required. Although endotracheal intubation can be performed under

TABLE 65-1 -- Specific Pediatric Diseases and Their Anesthetic Implications

Disease	Implications
Respiratory System	
Asthma	Intraoperative bronchospasm that may be severe Pneumothorax Optimal preoperative medical management essential; may require preoperative steroids
Difficult airway	May require special equipment and personnel Should be anticipated in children with dysmorphic features or acute airway obstruction as in epiglottitis or laryngotracheobronchitis or with airway foreign body Patients with Down syndrome may require evaluation of atlanto-occipital joint Patients with storage diseases may be at high risk
Bronchopulmonary dysplasia	Barotrauma with positive pressure ventilation Oxygen toxicity, pneumothorax a risk
Cystic fibrosis	Airway reactivity, bronchorrhea Risk of pneumothorax, pulmonary hemorrhage Atelectasis Assess for cor pulmonale
Sleep apnea	Must rule out pulmonary hypertension and cor pulmonale Requires careful postoperative observation for obstruction
Cardiac	Need for antibiotic prophylaxis for subacute bacterial endocarditis Use of air filters; careful purging of air from intravenous equipment Need to understand effects of various anesthetics on the hemodynamics of specific lesions Preload optimization and avoidance of hyperviscous states in cyanotic patients Possible need for preoperative evaluation of myocardial function and pulmonary vascular resistance Provide information about pacemaker function and ventricular device function
Hematologic	
Sickle cell	Possible need for simple or exchange transfusion based on preoperative Hgb and per cent Hgb S Importance of avoiding acidosis, hypoxemia, hypothermia, dehydration, and hyperviscosity states

Oncology	Pulmonary evaluation of patients who have received bleomycin, *bis*-chloroethyl-nitrosourea, chloroethyl-cyclohexyl-nitrosourea, methotrexate, or radiation to the chest Avoidance of high oxygen concentration Cardiac evaluation of patients who have received anthracyclines; risk of severe myocardial depression with volatile agents Potential for coagulopathy
Rheumatologic	Limited mobility of temporomandibular joint, cervical spine, arytenoid cartilages Requires careful preoperative evaluation May be difficult airway
Gastrointestinal	
Esophageal, gastric	Potential for reflux and aspiration
Liver	High overall morbidity and mortality in patients with hepatic dysfunction Altered metabolism of some drugs Potential for coagulopathy
Renal	Altered electrolyte and acid-base status Altered clearance of some drugs Need for preoperative dialysis in selected cases Succinylcholine to be used with extreme caution and only when serum potassium level is recently shown to be normal
Neurologic	
Seizure disorder	Avoid anesthetics that may lower threshold Ensure optimal control preoperatively Preoperative anticonvulsant levels
Increased intracranial pressure	Avoid agents that increase cerebral blood flow Avoid hypercarbia
Neuromuscular disease	Avoid depolarizing relaxants; at risk for hyperkalemia May be at risk for malignant hyperthermia
Developmental delay	May be uncooperative at induction
Psychiatric	Monoamine oxidase inhibitor (or cocaine) may interact with meperidine, resulting in hyperthermia and seizures Selective serotonin reuptake inhibitors may induce or inhibit various hepatic enzymes that may alter anesthetic drug clearance Illicit drugs may have adverse effects on cardiorespiratory homeostasis and may potentiate the action of anesthetics
Endocrine	
Diabetes	Greatest risk is unrecognized intraoperative hypoglycemia; if insulin is administered, monitor blood glucose level intraoperatively; must provide glucose and insulin with adjustment for fasting condition and surgical stress
Skin	
Burns	Difficult airway Risk of rhabdomyolysis and hyperkalemia from succinylcholine Fluid shifts Bleeding Coagulopathy
Immunologic	Retroviral drugs may inhibit benzodiazepine clearance Immunodeficiency requires careful infection control practices May require cytomegalovirus-negative blood products, irradiation, or leukofiltration
Metabolic	Careful assessment of glucose homeostasis in infants

Hgb = hemoglobin.

Box 65-3. Definitions of Anesthesia Care

Monitored anesthesia care: Monitored anesthesia care is a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.

Monitored anesthesia care includes all aspects of anesthesia care: a preprocedure visit, intraprocedure care, and postprocedure anesthesia management.

During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, which may include some or all of, but not limited to, the following:

- Monitoring of vital signs, maintenance of the patient's airway, and continual evaluation of vital functions
- Diagnosis and treatment of clinical problems that occur during the procedure
- Administration of sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary to ensure patient safety and comfort
- Provision of other medical services as needed to accomplish the safe completion of the procedure
- Anesthesia care often includes the administration of medications for which the loss of normal protective reflexes or loss of consciousness is likely. Monitored anesthesia care refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure. If, for an extended period of time, the patient is rendered unconscious and/or loses normal protective reflexes, this will be considered a general anesthetic.

Light sedation: Administration of anxiolysis and/or analgesia that obtunds consciousness but does not obtund normal protective reflexes (cough, gag, swallow, hemodynamic reflexes).

Deep sedation: Sedation that obtunds consciousness and normal protective reflexes or possesses a significant risk of blunting normal protective reflexes (cough, gag, swallow, hemodynamic reflexes).

General anesthesia: Administration of hypnosis, sedation, and analgesia that results in loss of normal protective reflexes.

Regional anesthesia: Induction of neural blockade (either central, neuraxial, epidural, or spinal; or peripheral nerve block, e.g., digital nerve block, brachial plexus block), which provides analgesia and is associated with regional motor blockade. Consciousness is not obtunded by regional anesthesia. Special expertise is required. Frequently, in children, anxiolysis and sedation is also necessary for this technique to be successful. Regional anesthesia (e.g., caudal epidural blockade) is used to supplement general anesthesia and provide postoperative analgesia.

Local anesthesia: Provision of analgesia by local infiltration of an appropriate anesthetic agent. Does not require the presence or involvement of anesthesiology, although an anesthesiologist may provide local anesthesia services.

postoperative analgesia.

Local anesthesia: Provision of analgesia by local infiltration of an appropriate anesthetic agent. Does not require the presence or involvement of anesthesiology, although an anesthesiologist may provide local anesthesia services.

No anesthesiologist: An anesthesiologist will not be involved in the care of the child in any way.

deep inhalational anesthesia with respiratory depression and obtunded cough and gag reflexes, the depth of anesthesia required to ablate airway reflexes is very close to that which induces hemodynamic instability. After anesthetic induction, intravenous access is secured and anesthesia is deepened with intravenous agents. Muscle relaxation with intravenous, nondepolarizing muscle relaxants is induced to facilitate endotracheal intubation. Succinylcholine is rarely used. After paralysis is induced, direct laryngoscopy and airway intubation can be performed. The correct endotracheal placement of the endotracheal tube is confirmed by direct laryngoscopy, end-tidal CO_2 measurement, endotracheal tube fogging, and bilateral, equal breath sounds during positive pressure ventilation.

After endotracheal intubation, spontaneous ventilation may be permitted, if muscle relaxants have either not been used or have worn off; however, it is routine to provide controlled mechanical ventilation. When the child is completely anesthetized, positioned for surgery, and hemodynamically stable and maintenance anesthesia is achieved, the surgery can begin.

Inhalational Anesthetics

General anesthesia may be induced and maintained by either inhalation or intravenous routes. Inhalational anesthetics include halothane, enflurane, isoflurane, sevoflurane, and desflurane. Halothane is the prototypical pediatric inhalational anesthetic agent; its use has decreased since the availability of isoflurane and sevoflurane. Enflurane is rarely used in children.

The minimal alveolar concentration (MAC) of an inhalational anesthetic is the alveolar concentration that provides sufficient depth of anesthesia for surgery in 50% of patients. For potent inhalational agents, the alveolar concentration of anesthetic reflects the arterial concentration of anesthetic in the blood perfusing the brain. Thus, the MAC level is an indication of anesthetic potency and is analogous to the ED_{50} of a drug. MAC is age dependent, is lower in premature infants than in full-term infants, and decreases from term through infancy to preadolescence. In adolescence, MAC again increases, falling thereafter. Inhalational anesthetic agents are poorly soluble in blood but rapidly equilibrate between alveolar gas and blood. The less soluble an anesthetic agent is in blood (low blood gas partition coefficient), the more rapid are both the induction and the emergence from inhalational anesthesia. Sevoflurane (0.69) and desflurane (0.42) have lower blood gas partition coefficients (the ratio of anesthetic concentration in the blood compared with the alveolar gas at equilibrium) than halothane (2.4).

Respiratory Effects

The advantages of inhalational anesthesia are rapid onset, rapid offset, convenient route for delivery and excretion (respiratory), and their ability to provide profound analgesia and amnesia. However, inhalational anesthetics are all airway irritants and, in low doses, can cause laryngospasm. All inhalational anesthetics depress ventilation in a dose-dependent manner. One MAC of inhalation anesthesia

decreases minute ventilation by approximately 25%, resulting in smaller tidal volumes and decreased respiratory rates. Thus, expired CO_2 and Pa_{CO_2} increase. One MAC of anesthesia also decreases end-expiratory lung volume (EELV) to below functional residual capacity (FRC) by about 30%. Small lung volumes result in decreased lung compliance, increased total pulmonary resistance, increased work of breathing, and increased intrapulmonary arteriovenous shunting and a restrictive lung defect. Inhalational anesthetics also shift the CO_2 response curve to the right, thus decreasing, but not ablating, the increase in minute ventilation with increasing Pa_{CO_2} .

Inhalational anesthetics may induce apnea and hypoxia in premature infants and newborns and are less frequently used in premature infants and children. General anesthesia always necessitates endotracheal intubation and controlled mechanical ventilation. In older children, spontaneous breathing through a mask, or a laryngeal mask airway (LMA), without controlled ventilation, is possible for shorter operations. The decreased EELV and increased work of breathing always necessitates increased inspired oxygen tension.

Cardiovascular Effects

The cardiovascular effects are depressed cardiac output and peripheral vasodilation; therefore, hypotension is frequent. This is accentuated in hypovolemic patients. This hypotensive effect is more pronounced in neonates than older children and adults. Inhalational anesthetics also decrease baroreceptor and heart rate responses. At one MAC of halothane, cardiac output is depressed approximately 25%. The ejection fraction is

TABLE 65-2 -- Selected Drugs Used in Anesthesia

Drug	Uses and Implications
Muscle Relaxants	Used to facilitate endotracheal intubation and maintain muscle relaxation
Succinylcholine (SDC)	A depolarizing neuromuscular blocking agent with rapid onset and offset properties Associated with the development of MH in susceptible patients Degraded by plasma cholinesterase, which may be deficient in some individuals and result in prolonged effect Fasciculations may be associated with immediate increases in intracranial and intraocular pressure as well as postoperative muscle pain
Pancuronium, vecuronium, *cis*-atracurium, d-tubocurarine (curare)	Nondepolarizing neuromuscular blockers Less rapid onset than SDC but longer acting Pancuronium is vagolytic, which may be of benefit in newborns, who have high levels of vagal tone Vecuronium and rocuronium are metabolized by the liver and excreted in bile *Cis*-atracurium is metabolized by plasma cholinesterase and therefore may be of benefit in patients with hepatic or renal disease; curare releases histamine and is long acting
Hypnotics	Used to induce a state of unconsciousness
Thiopental	Rapidly acting hypnotic, but not an analgesic Offset is by redistribution, not by metabolism May cause hypotension because of its myocardial depressant effects and by vasodilation Causes respiratory depression Releases histamine and may be associated with bronchospasm in susceptible individuals Increases seizure threshold
Ketamine	Hypnotic analgesic and amnestic Causes sialorrhea and should be co-administered with an antisialogogue such as atropine or glycopyrrolate May be associated with laryngospasm Causes endogenous catecholamine release, tachycardia, and bronchodilation Increases intracranial and intraocular pressure Decreases seizure threshold
Etomidate	Cardiovascular stability on induction with no increase in intracranial pressure May inhibit corticosteroid synthesis Associated with myoclonus, potential difficulty with assisted ventilation, and pain on injection
Propofol	Rapidly acting hypnotic, amnestic but not analgesic Like pentothal, may cause hypotension Causes respiratory depression May increase seizure threshold Great utility in titrated doses for sedation and with local anesthetic and short-acting opioid for outpatient procedures May suppress nausea
Sedative-Anxiolytics	

Benzodiazepines	May produce sedation, anxiolysis, or hypnosis, depending on dose May produce antegrade but not retrograde amnesia All raise seizure threshold, are metabolized by the liver, and depress respiration, especially when administered with opioids Frequently administered as premedicants Diazepam may be painful on injection and has active metabolites Midazolam can be administered by various routes and has a short half-life Lorazepam has no active metabolites Sedation effected by all benzodiazepines may be reversed by flumazenil, but respiratory depression may not be reliably reversed
Analgesic-Sedatives	
Opioids	Gold standard for providing analgesia May cause respiratory depression Morphine and, to a lesser extent, hydromorphone may cause histamine release The synthetic opioids fentanyl, sufentanil, and short-acting alfentanil may have a greater propensity to cause chest wall rigidity when administered rapidly or in high doses and are also associated with the rapid development of tolerance; these three drugs have particular utility in cardiac surgery because of the hemodynamic stability associated with their use Remifentanil is an ultra–short-acting synthetic opioid that is metabolized by plasma cholinesterase; it may have particular utility when deep sedation and analgesia are required along with the ability to assess neurologic status intermittently
Inhalational Agents	
Nitrous oxide	Amnesia and mild analgesia at low concentrations Danger of hypoxic mixture if oxygen concentration is not monitored and preventive safety mechanisms are not in place
Potent vapors	"Complete anesthetics"—they induce a state of hypnosis, analgesia, and amnesia All are myocardial depressants, and some are vasodilators All are triggers in MH-susceptible individuals Isoflurane and enflurane are fluorinated ethers and isomers Enflurane may lower seizure threshold Halothane has been the gold standard for performing inhalation induction of anesthesia in children, but sevoflurane, a newer drug, is also well tolerated and has more rapid kinetics (onset and offset) because of its low solubility in blood All are bronchodilators at equipotent concentrations Isoflurane, enflurane, and especially desflurane are associated with a higher incidence of laryngospasm, when used for anesthetic induction, than either halothane or sevoflurane Halothane may be associated with an acute fulminant hepatitis, although this is extremely rare in children.

MH = malignant hyperthermia.

decreased by about 25%. At MAC doses of halothane, heart rate is frequently increased; however, as inhalational anesthetic concentration increases, bradycardia may result, whereas profound bradycardia during anesthesia may indicate an overdose. Halothane and related agents sensitize the heart to catecholamines and may produce arrhythmias. Inhalational anesthesia also blunts the hypoxic pulmonary vasomotor response in the pulmonary circulation, a further factor that contributes to hypoxemia during inhalational anesthesia.

The effect of inhalational anesthesia is decreased oxygen delivery. Perioperatively, catabolism is enhanced and oxygen demands are increased. Therefore, there may be a profound

imbalance between oxygen demand and oxygen delivery. Development of a metabolic acidosis perioperatively may reflect this imbalance. Because cardiovascular depressant effects of inhalational anesthesia are greater in premature and newborn infants they are of limited use in these patients. They are widely used for the induction and maintenance of anesthesia in older children.

All inhalational anesthetic agents cause cerebrovasodilation. Halothane is a more potent cerebrovasodilator than sevoflurane or isoflurane. Thus, in children with elevated intracranial pressure, impaired cerebral perfusion, and head trauma, and in premature neonates at risk for intraventricular hemorrhage, halothane and other inhalational agents should be used with extreme caution. Although inhalational anesthetic agents decrease cerebral oxygen consumption, they may disproportionately decrease blood flow, thus worsening oxygen delivery.

Specific Anesthetics

Halothane.

Agents that are more pleasant to breathe and induce anesthesia more rapidly have replaced halothane (see earlier and later). Halothane hepatitis is a well-recognized sequelae of halothane and is most likely an idiosyncratic, allergic response. The incidence of hepatitis, which may be mild, leading to elevated levels of liver enzymes and jaundice, or severe, leading to acute hepatic necrosis, occurs at a rate of between 1:6,000 and 1:35,000 cases in adults. This appears to be more rare in children and occurs in between 1:80,000 and 1:200,000 exposures in children. There is no reason to particularly avoid halothane in children with liver disease.

Isoflurane.

Isoflurane maintains cardiac output and cerebral perfusion better than halothane. The therapeutic ratio for inducing anesthesia without hemodynamic instability is greater for isoflurane. It is also less of a respiratory depressant than halothane. Isoflurane is pungent and a significant airway irritant with an unacceptably high incidence of complications, such as laryngospasm. Emergence from anesthesia with isoflurane is quite smooth and faster than with halothane. Cerebral blood flow is only minimally affected, and cerebral oxygen delivery is maintained. Isoflurane is not implicated in hepatic disease. Because it is not a suitable induction agent, induction with halothane or sevoflurane, and maintenance with isoflurane, is common pediatric anesthesia practice.

Sevoflurane.

Sevoflurane has a low blood gas partition coefficient, predicting rapid alveolar equilibration and a faster rate of induction. Sevoflurane is not a significant airway irritant and leads to a smoother induction than isoflurane and a quicker one than with halothane. Sevoflurane appears to have less hemodynamic effects than halothane; the profile of respiratory effects at one MAC appears similar. Emergence from sevoflurane is quite rapid; however, there is a significant amount of emergence delirium, especially if pain has been inadequately controlled. This can be blunted with pretreatment with midazolam and adequate use of opioid narcotics; however, these delay recovery from anesthesia.

The major use of sevoflurane is induction of inhalational anesthesia in children. Because isoflurane is less expensive and has a similar physiologic profile to sevoflurane, anesthesia is maintained with isoflurane. Metabolism of sevoflurane yields free fluoride, which may cause renal damage and, thus, the U.S. Food and Drug Administration has restricted use of sevoflurane to less than 2 MAC hours, preferably with fresh gas flow rates in excess of 2?L/min.

Desflurane.

Desflurane has the lowest blood gas solubility coefficient (0.42) of commonly used anesthetics. It would be predicted that desflurane would provide rapid induction and emergence from anesthesia. Unfortunately, it is a potent airway irritant and causes coughing, breath holding, and laryngospasm during induction and is unsuitable for induction.

Nitrous Oxide (N_2O).

Nitrous oxide is a tasteless, colorless, odorless gas with potent analgesic properties. It induces a state of euphoria (laughing gas). The MAC of nitrous oxide is greater than 1, and therefore it is not suitable as a sole agent to maintain anesthesia. Nevertheless, nitrous oxide has few complications and little or no hemodynamic or respiratory depression. Commonly, during maintenance of anesthesia the inhalational gas mixture is 70% nitrous oxide and 30% oxygen, with the addition of an inhalational anesthetic or potentiation of analgesia with an opioid or hypnotic agent. It has a remarkably low blood gas partition (0.47), so it rapidly reaches alveolar equilibrium. Induction with and emergence from nitrous oxide–induced anesthesia is quite rapid. The deleterious effects of nitrous oxide are a suspicion of increased postoperative emesis and, in long-term use (days), bone marrow suppression. There is no evidence that there are harmful sequelae of the use of nitrous oxide for routine pediatric anesthesia. Nitrous oxide is a potent analgesic that is safely used in a mixture of 50% nitrous oxide and oxygen (Entonox) in obstetrics and emergency departments to provide analgesia. Although this combination appears to be quite safe, it will potentiate respiratory depressive effects of narcotics and its use, in combination with any other sedative, hypnotic, or narcotic agent requires very close monitoring, because it may produce general anesthesia.

Intravenous Anesthetic Agents

Anesthesia can be both induced and maintained with either boluses or continuous infusions of intravenous anesthetic agents. Intravenous anesthetics include barbiturates, narcotics, benzodiazepines, and miscellaneous drugs, such as ketamine. Intravenous anesthetic agents can induce anesthesia more rapidly than inhalational anesthetics, with fewer complications. On the other hand, an intravenous line needs to be placed and, unless intravenous access is already obtained, inhalation induction may remain the preferred route. For children arriving in the operating room with intravascular access, intravenous induction should be routine, because it rapidly takes the child from awake to anesthetized with less hemodynamic and cardiorespiratory compromise. All intravenous agents affect cardiorespiratory function. The one exception to this may be ketamine, which, in lower doses, releases catecholamines, which maintain cardiac function and blood pressure.

Barbiturates.

The most commonly used barbiturate for intravenous induction is sodium thiopental. This drug depresses respiration, induces apnea, and can cause hypotension in the hypovolemic patient. It generally has little impact on myocardial function and in the euvolemic well child is a useful anesthetic induction agent. Induction with 3–5?mg/kg of thiopental usually produces 5 to 10?min of unconsciousness within seconds. Although loss of consciousness can rapidly be induced, barbiturates do not provide analgesia. After intravenous induction with sodium thiopental, maintenance anesthesia can be established using benzodiazepines, intravenous narcotics, or

inhalational anesthetics.

Pentobarbital is commonly used for sedation in children. Pentobarbital is an intravenous drug that induces loss of consciousness. It is also a potent respiratory depressant, particularly in conjunction with narcotics and benzodiazepines. It has a very prolonged effect. It is not an analgesic agent, and painful procedures cannot be performed with pentobarbital sedation without supplemental analgesia. Pentobarbital sedation deep enough for anxiolysis and nonpainful procedures generally results in prolonged sleep. Its potency and long duration of action make it difficult to titrate. It is not an ideal drug for sedation for short or painful procedures.

Sodium methohexitone (Brevital) is another intravenous induction agent. It is not dissimilar from sodium thiopental and has a similar spectrum of respiratory depression.

Propofol.

Propofol is the most commonly used intravenous induction agent in pediatric anesthesiology and has a rapid onset. In doses between 2–3?mg/kg, propofol induces less respiratory depression than thiopental but does produce hypotension. Propofol can sometimes burn and itch on injection; this frequently leads the child to withdraw or respond after a propofol bolus. After induction of anesthesia, propofol is also a useful agent for maintaining hypnosis and amnesia and can be used as a sole anesthetic agent for nonpainful procedures such as radiotherapy, MRI, and CT scanning. Combined with narcotics, it provides excellent, brief anesthesia for painful procedures such as lumbar punctures and bone marrow aspiration. Propofol is a general anesthetic agent and will obtund airway reflexes, respiration, and hemodynamic function and should not be considered as a “sedation” agent. Although hemodynamic stability, and even spontaneous respirations, can be maintained with propofol sedation, its use in children younger than age 12 yr for prolonged sedation over several hours to days is associated with hemodynamic collapse, metabolic acidosis, cardiac failure, profound shock, and death. Its use for prolonged sedation (>12?hr) in the critical care setting in children is contraindicated.

Ketamine.

Ketamine rapidly induces general anesthesia and lasts for 15 to 30?min when given at 2?mg/kg IV. It has few side effects and can maintain adequate blood pressure and cardiac output. Ketamine is also effective given either intramuscularly, subcutaneously, or even orally; however, the dose must be increased for these alternative routes. Ketamine is not only a hypnotic agent, providing obtundation and loss of consciousness, but also an analgesic agent and can act as a sole intravenous agent for the provision of a general anesthesia. In low doses, airway reflexes and spontaneous ventilation may be maintained; in higher doses, loss of airway reflexes, apnea, and respiratory depression occur. It is unwise to rely on ketamine to prevent aspiration of gastric contents during deep sedation. Intravenous ketamine is a useful general anesthetic agent for short procedures.

Ketamine produces disturbing postanesthetic dreams and hallucinations. These can occur during emergence from anesthesia or up to weeks later. In adults, the incidence is 30–50%. In prepubertal children, it may be between 5%–10%. Premedication with a benzodiazepine, such as midazolam, greatly reduces these sequelae, and a benzodiazepine is routinely added in children receiving ketamine anesthesia. The other side effect of ketamine is that it is a potent secretagogue and bronchial secretions are enhanced. A drying agent, such as atropine or glycopyrrolate, is administered before the administration of ketamine.

Ketamine is a bronchial smooth muscle relaxant (bronchodilator) and is a useful agent for sedating asthmatic patients and others in the intensive care unit (ICU). Ketamine has been reported to increase intracranial pressure and is, therefore, not indicated in patients at risk for elevated intracranial pressure. Ketamine can increase myocardial oxygen demand and should be used cautiously in patients with impaired myocardial oxygen delivery or cardiac outflow tract obstruction.

Narcotics.

Narcotics are superb analgesic agents providing analgesia for painful procedures and postprocedural pain. Narcotics are well described in Chapter 66 . Large doses of morphine, combined with nitrous oxide, provide adequate analgesia for painful procedures and surgery. Narcotic agents suppress the CO_2 response, can induce apnea, and are respiratory depressants. Morphine is frequently associated with hypotension and bronchospasm from histamine release, and its use is cautioned in children with asthma. Morphine is a long-acting agent, and an equivalent dose per kilogram gives much higher blood levels in neonates than in older children, with plasma concentrations approximating three times those in adults. This is caused by a prolonged elimination half-life (14?hr) as compared with adults (2?hr). Because of the prolonged activity and hemodynamic instability induced by morphine, the synthetic fentanyl class of narcotics has largely replaced morphine.

Fentanyl is an effective agent to provide pain relief, analgesia, and sedation for painful procedures with a shorter duration of activity and more stable hemodynamic profile than morphine. In equal analgesic doses, all narcotics are equally potent respiratory depressants. Other anesthetic agents potentiate this respiratory depression, whether they are inhalational anesthetics or intravenous barbiturates or benzodiazepines.

Fentanyl use in a 30–50?µg/kg dosing range provides absence of abnormal hemodynamic response to surgery and provides stable operative conditions. Effective analgesia and anesthesia can be provided with intravenous fentanyl in a 2–3?µg/kg bolus followed by a 1–3?µg/kg/hr continuous infusion. Hemodynamic effects can be blunted and recall totally obtunded using a nitrous anesthetic technique, although muscle tone may remain high and spontaneous movements can occur. Nitrous-narcotic anesthetics usually contain a nondepolarizing muscle relaxant during maintenance anesthesia. If the patient is going to be extubated and resume spontaneous ventilation, reversal of the muscle relaxant is necessary.

Other synthetic narcotics—sufentanil, alfentanil, and remifentanil—have gained

some use; fentanyl is the most commonly used. The indications and use for these other synthetic narcotics are guided by their different potencies and altered pharmacokinetics. Both sufentanil and alfentanil have been used for cardiac anesthesia, but they have a different potency than fentanyl. Alfentanil appears to have an increased incidence of muscle rigidity, convulsions, and prolonged respiratory depression compared with fentanyl and is not used in children.

Remifentanil has a very rapid onset and offset of action. In doses of 0.25?µg/kg/min, surgical anesthesia can be maintained. Its short half-life and rapid offset are advantageous for rapid emergence. Unfortunately, the rapid offset of action also leads to postprocedural and postoperative pain and requires analgesic supplementation, frequently with a narcotic, which removes the advantage of a short-acting narcotic anesthesia. Remifentanil may have a place for rapidly deepening anesthesia for particularly painful events or rapidly inducing analgesia. It is a potent respiratory depressant and provides no postprocedural analgesia, which limits its use.

Benzodiazepines.

Benzodiazepines induce hypnosis, anxiolysis, sedation, and amnesia and have anticonvulsant activity. In larger doses they cause respiratory depression and apnea; they are synergistic with narcotics and barbiturates in their respiratory depressant effects. Benzodiazepines inhibit neurally mediated ?-aminobutyric acid receptors to induce sedation.

The most commonly used benzodiazepine in pediatric anesthesia is midazolam. It is short acting and water soluble and can be injected intravenously without pain. It is a potent hypnotic-anxiolytic-anticonvulsant and is approximately four times more potent than diazepam. In anxiolytic doses, midazolam (0.15?mg/kg) has no impact on respiratory rate, heart rate, or blood pressure and provides excellent preoperative sedation, frequently accompanied by amnesia. It can be administered orally, nasally, rectally, intravenously, or intramuscularly. Use of *oral* midazolam at a dose between 0.5–1.0?mg/kg, mixed in sweet flavored syrup, induces anxiolysis in approximately 90% of children. Although there are no hemodynamic, oxygenation, or respiratory depressant effects at this dose level, when midazolam is used as a sole agent, children may frequently lose their balance and head control, may have blurred vision, and may, very rarely, become dysphoric. A child sedated with midazolam should not be left unattended and is not safe walking. The vast

majority of children rapidly accept an inhalational anesthetic mask after oral midazolam premedication

Complications During Induction of Anesthesia

The period between full wakefulness, with the child in control of airway reflexes, and general anesthesia, with total loss of control, is fraught with difficulty. During induction, laryngospasm, bronchospasm, vomiting, aspiration of gastric contents, and subsequent aspiration pneumonitis are a constant but rare occurrence. Concern for vomiting and aspiration dictates preanesthetic NPO guidelines and the indication for rapid sequence anesthetic induction.

Laryngospasm is the most common complication. During induction of anesthesia, especially with inhalational anesthetics, a period of excitement may occur. This period is associated with heightened airway reflexes, which can lead to coughing, gagging, laryngospasm, and bronchospasm. Laryngospasm is reflex closure of the larynx, which makes it impossible for the child to breathe or to ventilate the child. A child may be witnessed to be making violent respiratory efforts against a closed glottis, generating significantly negative intrathoracic pressure with impact on cardiovascular function and the risk of postobstructive pulmonary edema. Laryngospasm can be prolonged and hypoxia may ensue. Laryngospasm occurs in up to 2% of all anesthetic inductions in children younger than age 9 yr and is half as common in older patients. Laryngospasm occurs twice as frequently in children with active or recent upper respiratory tract infections (URIs). A history of passive smoking from environmental (parental) tobacco smoke increases the likelihood of laryngospasm by 10-fold and even more if the smoker is the child's mother.

Laryngospasm can be relieved during induction of anesthesia by deepening the anesthetic, either intravenously or by inhalational anesthesia (although with the glottis closed, further administration of inhalational anesthesia is not possible). Muscle relaxation will relieve laryngospasm, and this may be, in an acute situation, an indication for succinylcholine. Constant positive airway pressure by someone skilled in airway management to ensure patency of the soft tissues of the oropharynx may be beneficial in alleviating the laryngospasm. Laryngospasm may also occur during emergence as a state of excitement is again traversed between deep anesthesia and wakefulness.

Bronchospasm can occur during induction, either in response to histamine release owing to many of the anesthetic agents or a hyperexcitable stage. Endotracheal intubation may also induce bronchospasm during induction. Bronchospasm during induction is particularly common in children with asthma. Bronchospasm secondary to intubation in a patient with reactive airway disease can be severe, associated with life-threatening hypoxemia and a profound inability to ventilate the child. The use of histamine-releasing anesthetic agents has been associated with total airway obstruction, respiratory failure, and cardiac arrest. Environmental tobacco smoke is a risk factor.

Other pulmonary problems with induction of anesthesia include massive atelectasis with hypoxemia, impaired ventilation and perfusion, blunted hypoxic pulmonary-vasoconstriction, and increased airway secretions with decreased bronchociliary function. Hypersecretion is prevented by the routine use of antisialagogues such as atropine. The newer inhalation agents are less potent secretagogues, and the use of atropine premedication is less common but is probably indicated if ketamine is used.

Hemodynamic complications on induction include hypotension, which in hypovolemic patients can be profound, decreased myocardial function, which in patients with compromised cardiac function can be severe, and tachycardia and cardiac dysrhythmias. Inhalational anesthetics sensitize the myocardium to circulating catecholamines, and induction and excitement are associated with a

hypercatecholaminergic state.

Parental Presence During Induction of Anesthesia

Parents may expect to be with their child during the induction of anesthesia. Removing a terrified child from the comforting arms of a parent is stressful for the child, the parent, and the caregivers. If this parental separation cannot comfortably be achieved with preoperative psychoprophylaxis and behavioral modification, including education and desensitization to the operative environment, or with pharmacologic aids, such as preoperative medications including benzodiazepine and barbiturates, then there may be a need to defer parent-child separation until general anesthesia has been induced. Preoperative oral benzodiazepine premedication more frequently provides calm, smooth induction conditions than parental presence without pharmacologic preparation. Although parental presence in the hands of a confident, competent anesthesia practitioner can replace the need for preoperative medication, it does not reliably predict smooth induction. Parental presence during induction appears neither to decrease emergence phenomena nor the incidence of postoperative behavioral changes and does not appear to add an advantage for the child over that provided by preoperative sedative medication, such as oral midazolam.

MAINTENANCE OF ANESTHESIA

Maintenance of anesthesia is the period between induction and emergence. The child should be asleep, unaware of pain, unresponsive either with motion or hemodynamic responses to painful stimuli, and homeostatically supported. The child is comatose, without protective airway reflexes or suppressed or absent respiration, and has received drugs that suppress hemodynamic maladaptive responses. The child is also exposed to surgical trauma and there may be blood loss and significant fluid shifts (third spacing), decreased intravascular volume, and hypothermia.

Anesthesia is usually maintained with nitrous oxide, an inhalational anesthetic such as isoflurane, and a narcotic for intraoperative analgesia, potentiation and deepening of anesthesia, and postoperative analgesia. A benzodiazepine is added either during premedication or intraoperatively to supplement hypnosis and amnesia. A nondepolarizing muscle relaxant (vecuronium or rocuronium) completes the pharmacologic maintenance of anesthesia. Agents can be given by continuous inhalational anesthesia or by continuous or bolus intravenous infusion.

During maintenance, the child may either breathe spontaneously through an anesthetic mask or endotracheal tube or be mechanically ventilated. All general anesthetic agents lead to decreased end-expiratory lung volume, generally lower than FRC, with an increase in pulmonary closing capacity and increased intrapulmonary shunt. Hypoxia would occur without supplemental oxygenation. These effects are compounded by respiratory depressant effects and the depressed CO_2 response curve. Therefore, it is generally considered that anesthetics that last for more than 1?hr require endotracheal intubation and positive pressure ventilation. For long procedures, spontaneous breathing through a mask is possible; however, in smaller children where the surgical field and the airway may be close together, the need to maintain a patent airway necessitates endotracheal intubation.

Muscle relaxation to facilitate endotracheal intubation was once accomplished with succinylcholine. Succinylcholine has a large risk profile and is associated with postoperative pain (muscle spasms); hyperkalemia; elevated intracranial, intraocular, and intragastric pressures; malignant hyperthermia; and myoglobinuria and renal damage. Succinylcholine is rarely used

---

except to provide rapid relief of laryngospasm. Intubation of the airway is facilitated with a nondepolarizing muscle relaxant of short-acting duration; for procedures that last more than 40?min, vecuronium and alcuronium are adequate. After intubation of the airway, the decision must be made whether to maintain muscle relaxation to facilitate surgery or whether to allow the child to resume spontaneous respiration. Prolonged use of nondepolarizing muscle relaxant is common practice but may contribute to postoperative respiratory compromise.

Thermoregulation is critical during anesthesia. The absence of movements and the inhibition of shivering lead to difficulty in thermogenesis. All factors of heat loss, convection, radiation, evaporation, and conduction, occur during anesthesia. Humidification and warming of inspired air is required. Additional warming devices are quite commonly used, such as the BAIR hugger. General anesthetic agents increase the interthreshold range (the minimal temperature change that will lead to sympathetic response, generally 0.3°C). Although temperature sensing may remain normal, autonomic response to hypothermia is not triggered. Anesthetic agents cause vasoparesis, and this further impairs thermoregulation and causes increased heat loss. In newborns, inhalational anesthetics inhibit nonshivering thermogenesis from brown fat, placing them at higher risk for hypothermia.

Intraoperative Monitoring

Routine monitoring includes electrocardiography, with common chest and limb leads that monitor rate, rhythm, and ST segment depression. Pulse oximetry and monitoring of end-tidal CO_2 are routine. The fraction of inspired oxygen is continuously measured. The fraction of anesthetic vapor in the inspiratory (and expired) gas mixture can be continuously monitored, and the mixture of oxygen, air, and nitrous oxide is continuously visualized, either through the use of rotameters or through direct measurement of the inspiratory gas mixture and digital display. Respiratory rate, tidal volume, and respiratory mechanics may be monitored intraoperatively (compliance and resistance). Blood pressure monitoring, with systolic, diastolic, and mean pressures is also routine. This can be done by Doppler ultrasonic or pneumatic techniques.

Fluid Maintenance During Surgery and Anesthesia

Fluid maintenance differs from the normal resting state owing to the effects of anesthesia and surgery. Patients who are unconscious and immobile have lost venous pump mechanisms and have venous pooling in the periphery. Anesthetic agents cause vasodilation, and patients develop relative hypovolemia. Intravascular volume expansion is frequently required after the induction of anesthesia to maintain

adequate perfusion, tissue oxygenation, urine output, and blood pressure. This volume expansion can be an isotonic salt-containing solution (normal saline or lactated Ringer). Surgery may lead to increased autonomic responses as part of the surgical stress response, with vasoconstriction and intravascular volume contraction, diuresis, and intravascular volume loss from hemorrhage and from third space (interstitial space) fluid losses caused by the inflammatory response to stress. Abnormalities in the distribution of renal blood flow and secretion of antidiuretic hormone further complicate the regulation of intravascular volume.

Hypoglycemia due to preoperative fasting was a concern and supported the recommendations that infants and small children receive isotonic solutions with 5% glucose. The occurrence of hyperglycemia and potential neurologic injury during cardiopulmonary bypass, or during neurosurgery and other situations in which CNS injury can occur, and with the recognition that hypoglycemia is rare in non-neonates, has questioned the routine use of glucose-containing solutions. In neonates, glucose monitoring during and after anesthesia is indicated. In older children with normal nutritional status isotonic salt solutions are adequate. In children who are receiving parenteral alimentation with high glucose concentration solution (>10%), continuation of these glucose concentrations should be ensured to avoid hypoglycemia when these high concentration glucose solutions are stopped.

Intraoperative fluid maintenance includes (1) current maintenance fluids and replacement of maintenance deficits while NPO; (2) replacement of third space losses; and (3) replacement of extraordinary losses (hemorrhage). These should be, in infants, glucose-containing, isotonic fluids, such as D_5 W with 0.25 normal saline, or isotonic crystalloid solutions. A guideline for determining fluid deficits and maintenance requirement in the operating room is shown in Table 65–3 . Replacements of the fluid deficits should be done over the first 2 or 3?hr of the intraoperative management. Deficits are generally calculated as the number of hours that a child was NPO times the hourly maintenance rate for the child. Half of this is replaced during the first hour and one fourth during each of the subsequent 2?hr. If hypotension or tachycardia occur or persist in the early stages of the anesthetic, more rapid replacement of the deficit is indicated. The deficit is replaced with isotonic crystalloid solutions.

Third space losses are replaced with isotonic salt solutions. For large operations, such as abdominal or thoracic operations where there may be a large amount of evaporative loss, as well as a significant amount of third space losses, 8–10?mL/kg/hr of surgery is generally given as intravenous fluid replacement. For smaller operations, such as herniorrhaphy, pyloromyotomy, and minor cases, 3–5?mL/kg/hr of fluid replacement for third space losses is indicated. Even when surgery involves the extremities, and third space losses are minor, it is wise to give an additional 1–2?mL/kg/hr to replace third space losses.

Crystalloid is indicated for blood loss at 3?mL of crystalloid per milliliter of blood loss. This formula could be reduced somewhat if blood is replaced on a milliliter per milliliter basis with packed red blood cells or whole blood equivalent. The use of albumin or other suitable colloid, such as fresh frozen plasma in neonatal surgery, also decreases the amount of crystalloid replacement for blood loss. During maintenance anesthesia, if large volume transfusions are required, warming the blood and crystalloid solutions avoids hypothermia.

Hemodynamic integrity, renal function, cerebral perfusion, thermoregulation, and adequate intraoperative cardiovascular function depend on adequate fluid replacement. With major surgery and the resultant systemic inflammatory response, capillary integrity is lost and losses of interstitial fluid are common. The tissue edema that occurs postoperatively is the result of the surgical stress and occurs whether or not intravascular volume is adequately replaced. Failure to replace this third space loss and restore intravascular volume leads to hypotension, shock, acidemia, and renal failure and further stimulates the systemic inflammatory response and worsens physiologic impairment.

RECOVERING FROM ANESTHESIA

Recovering from anesthesia includes emergence and postoperative recovery from surgery and anesthetics. Emergence describes the period of time and the physiologic response to decreasing depth of anesthesia during return to consciousness. During emergence there is decreased anesthetic effect, increased

TABLE 65-3 -- **Intraoperative Pediatric Fluid Replacement**

4?mL/kg/hr	1 to 10?kg
2?mL/kg/hr	10 to 20?kg
1?mL/kg/hr	per kg over 20?kg
Example: 22?kg child requires: (4 ×10) + (2 ×10) + (1 ×2) = 62?mL/hr	

stress responses, physiologic and psychologic responses to painful stimuli, excitement, and anxiety. Conscious realization of pain may lead to physiologic responses during emergence. The resumption of normal physiologic functions, such as spontaneous ventilation and improved hemodynamic function, occurs. For routine elective cases, the child should be fully conscious, with intact airway reflexes, the ability to follow simple commands, the effects of muscle relaxants reversed, and airway patency maintained before leaving the operating room. If the child is going to the ICU, or for surgical reasons the decision is made to leave the child intubated, then analgesia and sedation should be maintained along with mechanical ventilation in the postoperative period. Ideally, emergence should be as brief as possible, with maintenance of analgesia and anxiolysis and restoration of cardiorespiratory function. Inhalational anesthetic agents rapidly leave the system during ventilation, and muscle relaxants can be reversed; however, the effects of narcotics, benzodiazepines, and intravenous hypnotic agents may be prolonged.

It is possible to provide perfectly adequate general anesthesia with short-acting narcotics (remifentanil), short-acting muscle relaxants (rocuronium), and inhalational anesthesia. The effects of all of these may entirely dissipate within 5 to 10?min. This is not necessarily ideal because the child may have inadequate analgesia for

postoperative pain management and be emerging in an unfamiliar environment.

During emergence, the decision must be made whether to reverse the muscle relaxants. Long-acting, nondepolarizing muscle relaxants (vecuronium and pancuronium) can be reversed using neostigmine, an acetylcholinesterase inhibitor. Atropine, or glycopyrrolate, is frequently administered along with the anticholinesterase drug to prevent bradycardia to which children are particularly sensitive. If the child appears to be weak or have respiratory depression in the postoperative phase, consideration of prolonged neuromuscular blockade is indicated.

PACU

In the post-anesthetic care unit (PACU) the child is observed until there is recovery from anesthesia. Parents should be permitted to comfort their children in the PACU. Achievement of spontaneous breathing, adequate arterial saturations above 95%, and hemodynamic stability are key recovery end-points. The child should be arousable, responsive, and oriented before discharge from the PACU. Duration in the PACU will depend on whether the child is being discharged to an inpatient nursing unit, an ICU, a postrecovery area, or directly home. Discharge from the PACU depends on the child's overall functional status, not merely the physiologic end-points, but also the behavioral end-points, and the adequate provision of analgesia and control of postoperative nausea and vomiting. There are several scoring systems (Table 65–4) for determining whether a child is suitable to be discharged from the ICU.

Complications in the PACU

Respiratory Depression.

Prolonged emergence from anesthesia and respiratory depression can be caused by opioids or inadequate antagonism of neuromuscular blocking agents. Pain can cause significant hypoventilation, especially after thoracic or abdominal surgery. Delayed emergence from anesthesia can occur owing to retention of inhaled anesthetic agents worsened by hypoventilation. Hypothermia, especially in neonates, delays metabolism and excretion of anesthetics and also aggravates neuromuscular blockade. If respiratory depression is profound, then maintenance of the airway may require an oral airway. If the patient is severely depressed, endotracheal intubation and mechanical ventilation are indicated.

Only in rare cases, where opioid suppression is suspected, is reversal of the narcotic with naloxone indicated. The reversal of

narcotics with naloxone is not merely reversal of respiratory depression but also reversal of analgesia. A somnolent child with respiratory depression may become excited, agitated in severe pain, uncontrollable, and/or hypertensive after naloxone. Narcotic reversal necessitates bedside attention by the physician to monitor the child's behavioral, hemodynamic, and respiratory status. Naloxone is shorter acting than most narcotic analgesics.

Atelectasis is another respiratory complication occurring in the first 48?hr after anesthesia. Atelectasis raises the suspicion of an inhaled foreign body but is most likely caused by secretions and decreased respiratory effort secondary to pain. Microatelectasis may lead to postoperative infections. Aspiration pneumonia is another postoperative complication.

Postoperative stridor occurs in up to 2% of all pediatric patients. Use of uncuffed, atraumatic, nonirritant endotracheal tubes has decreased the incidence of airway trauma. The use of appropriately sized endotracheal tubes and assurance of a leak below 30?cm?H_2O pressure further decreases the risk of airway trauma. A prior history of stridor increases the likelihood of postoperative complications. Stridor may be severe enough post extubation to require re-intubation. Retractions and respiratory distress in the postoperative period should suggest this complication, and stridor or wheezing should confirm the diagnosis. Racemic epinephrine aerosols are effective therapy; however, their use requires prolonged observation owing to the potential of recurrence of the airway obstruction. Stridor in infants should suggest the need for overnight observation.

Hemodynamic instability is much less common in the PACU. Volume expansion may be required to maintain adequate blood pressure, peripheral perfusion, and urine output. Excessive volume replacement (>30?mL/kg) that is required to maintain blood pressure, perfusion, and urine output in the postoperative period is an indication of shock and occult bleeding and requires surgical consultation.

Emergence delirium is noted in less than 3% of children and is more common in ages 3 to 9 yr. In the immediate hours after surgery, the child may become extremely restless, combative, disoriented, screaming, crying, and poorly communicative. These children pose a danger to themselves. This phenomenon is more common when barbiturates are used as part of a premedication or induction and inhalational anesthetics or ketamine form part of the maintenance anesthetic. Although disorientation is common in the postanesthetic stage, erratic, delirious behavior requires attention with gentle restraint and comforting. Potential postoperative complications, such as hypoglycemia and hypoxemia, should be ruled out. Occasionally, it is necessary to sedate the child with benzodiazepines, although these prolong postanesthesia recovery time, and when they wear off emergence delirium may occur.

Postoperative Nausea and Vomiting (PONV).

After general anesthesia, as many as 40–50% of children may experience nausea and vomiting. Over 80% of all high-risk children receiving inhalational anesthesia experience postoperative nausea and vomiting. PONV may occur in the immediate postoperative period, within the first 1–2?hr, or can occur several hours after surgery and anesthesia. The etiology may be related to the stress and trauma of surgery, combined with the emetic effects of anesthetic agents. Pain is an important cause of nausea and vomiting. Unfortunately, narcotic analgesics also induce nausea and vomiting. Preoperative fasting does not decrease the incidence of nausea and vomiting. Indeed, hydration and glucose supplementation appear to be important factors in decreasing PONV. The use of analgesic agents other than narcotics (e.g., acetaminophen, ketorolac) and regional or local anesthesia is associated with less nausea and vomiting in the postoperative period.

PONV prolongs recovery room times, requires significant nursing attention, and increases the use of potent antiemetic agents (ondansetron and other serotonin antagonists). Droperidol is beneficial prophylactically and for established vomiting; metoclopramide is useful prophylactically. Droperidol must be used with caution, owing to the rare occurrence of a prolonged QT interval and ventricular arrhythmias. Ondansetron is very efficacious as a prophylactic and a treating agent for PONV. Ondansetron and other serotonin antagonists are recommended for high-risk patients (strabismus surgery) or for actual treatment of PONV.

All inhalational anesthetics are associated with PONV, and their replacement with a nitrous narcotic technique does not decrease PONV. The induction or maintenance of anesthesia with propofol may decrease PONV.

Thermoregulation and Malignant Hyperthermia.

In the PACU, thermoregulation remains abnormal for several hours. Shivering is common in the postoperative state, and a feeling of extreme coldness is common. Warm blankets are very comforting and seem to decrease shivering. Hypothermia, especially in neonates, leads to hypotension, bradycardia, acidosis, apnea, and prolongation of the effect of narcotics and neuromuscular blocking agents. Although there are deleterious effects of hypothermia, rewarming must be cautious to avoid burning and cutaneous hyperthermia. Hyperthermia, with temperatures in excess of (39℃), is of concern in the postoperative period. If this occurs within hours of an inhalational anesthetic, especially if succinylcholine was used, malignant hyperthermia must be suspected.

Malignant hyperthermia is an acute hypermetabolic syndrome that is triggered by inhalational anesthetic agents and succinylcholine. It resembles **neuroleptic malignant syndrome**. The onset of malignant hyperthermia may be acute, and its course may be fulminant and rapidly fatal. This condition, albeit rare (approximately 1:14,000 pediatric anesthetics) is a constant concern. The disease is familial, and hence a family history of death during anesthesia, or the history of a febrile reaction, should alert the anesthesiologist to its potential. Its clinical course is characterized by a rapid onset of fever, acidosis, hypercarbia, and increased expired CO_2 . High fever

(38.5–46°C, rising 1 degree every 5?min), muscle rigidity, metabolic acidosis, and hemodynamic collapse can occur. Death ensues from shock and cardiac dysrhythmias with unresponsive ventricular fibrillation. The mortality rate for malignant hyperthermia was once in excess of 70%. Aggressive therapy, including discontinuation of all inhalational anesthetic administration, correction of the metabolic acidosis, and treatment with the muscle relaxant sodium dantrolene, has reduced the mortality to less than 5%. Dantrolene and a kit containing supplies necessary to treat malignant hyperthermia should be present at every site where pediatric anesthesia is practiced.

Its exact genetic basis remains elusive owing to the diversity of triggering agents and the range of the response. Malignant hyperthermia is probably genetically heterogeneous, with over ten genes contributing to malignant hyperthermia susceptibility. Genetic mutations in the ryanodine receptor (the calcium channel of the sarcoplasmic reticulum) have been identified in malignant hyperthermia–susceptible swine, and a similar defect has been reported in 20–40% of humans with malignant hyperthermia.

Malignant hyperthermia appears to occur from a massive triggering of excitation-contraction coupling, sarcolemmal calcium release, and propagation of contraction by a complex biochemical process. Phospholipase A_2 activity is primarily triggered, increasing mitochondrial free fatty acids and stimulating calcium release. The prolonged ischemic contraction leads to myolysis with release of myoglobin, very high serum creatine phosphokinase (CPK) levels, and renal failure secondary to myoglobinuria. Malignant hyperthermia generally occurs within the first 2?hr of anesthesia but rarely can occur up to 24?hr later.

Certain phenomena are clues to the risk of developing malignant hyperthermia. The occurrence of masseter spasm during induction, with rigid clenching of the masseter muscles and an inability to open the mouth, may presage full-blown disease. Acute myoglobinuria associated with a malignant hyperthermia–triggering agent is another clue. The child may not be hypermetabolic or febrile but develops dark urine and high serum CPK levels with the risk of myoglobin-induced renal tubular damage. Dark urine after an anesthetic requires investigation for malignant hyperthermia. An elevated CPK value and heme-positive urine in the absence of red blood cells in the urine indicates a need for renal protection with mannitol and alkaline diuresis.

Certain myopathies are associated with the risk for malignant hyperthermia; these include Duchenne muscular dystrophy, Noonan phenotype, and, in children with history of ptosis, squint, scoliosis, and muscle cramping. It is wise to avoid the use of succinylcholine in children with myopathies.

Rapid therapy is essential. All known triggering agents must be stopped. Intravenous administration of dantrolene sodium (2.5?mg/kg IV) as an initial dose is given as soon as possible. Repeated doses are indicated by the persistence of muscle rigidity, acidosis, and tachycardia, up to a maximum dose of 10?mg/kg. After control of the symptoms, the patient should be observed for at least 24?hr after the laboratory values have returned to normal because relapse can occur.

Prevention of malignant hyperthermia in susceptible patients requires the avoidance of triggering agents, which include inhalational anesthetics. Most anesthesiology departments are

capable of delivering general anesthetics using anesthesia machines from which all traces of anesthetic vapors have been removed. Intravenous anesthesia and a nitrous-narcotic technique are safe. Dantrolene prophylaxis is not recommended because the disease is rapidly treatable and because the drug has respiratory depressant and muscle weakness. If a child is suspected of having malignant hyperthermia, the malignant hyperthermia hotline, 1-(800)-MHHYPER, should be notified. This will register susceptible patients and provides diagnostic and therapeutic information. Preanesthesia susceptibility testing includes genetic analysis of the ryanodine receptor gene, muscle biopsies, in vitro contraction studies, or possibly measuring muscle CO_2 production in response to intramuscular caffeine.

Postoperative Apnea.

Apnea within the first 24–48?hr after surgery and anesthesia in premature infants is common; both central and obstructive apnea (mixed apnea) may occur. The use of respiratory depressants may impair the respiratory control in neonates. Apnea is also a recognized stress response in neonates, and inadequate anesthesia is associated with increased apnea and respiratory complications in neonates.

The risk of developing postoperative apnea in premature neonates is inversely proportional to postconceptual age at the time of surgery. This risk is minimal by the time premature infants have reached the postconceptual age of 60 wk. Apnea is most common within the first 12?hr after surgery; postanesthetic apnea has been reported in premature infants up to 48?hr later. The incidence of apnea in full-term infants is debatable and not clearly demonstrated. It is generally agreed that general anesthesia should be avoided, except for emergent surgery, in full-term children younger than 44 wk postconceptual age. If surgery is required within the first month, overnight observation and monitoring is indicated. Theophyllines decrease the incidence of postoperative apnea; however, they do not ablate it and are, therefore, not routinely used. The safest course is to monitor premature infants younger than 60 wk postconceptual age and full-term infants younger than 1 mo old for at least 24?hr after anesthesia.

PREANESTHETIC EVALUATION

Most previous healthy children require minimal preoperative assessment. The American Society of Anesthesiologists classification system for anesthetic care is the ASA Physical Status classification, which has five levels and an additional classification of “E” for emergency surgery (Box 65–4).

For ASAPS-1 patients, a brief history, notation of medical allergies, and a physical examination, focusing on the airway, lungs, and cardiac function, are sufficient. All children being assessed for anesthesia risk should have a family history obtained for reactions to anesthetics, drug allergies, and for sudden death intraoperatively or hyperthermia after surgery, which may indicate malignant hyperthermia risk. In

children who have had a previous anesthetic, questions should be asked

Box 65-4. American Society of Anesthesiology Physical Status Classification

Class 1: Healthy patient, no systemic disease.

Class 2: Mild systemic disease with no functional limitations. (Mild chronic renal failure, iron deficiency anemia, mild asthma)

Class 3: Severe systemic disease with functional limitations. (Hypertension, poorly controlled asthma or diabetes, congenital heart disease, and cystic fibrosis)

Class 4: Severe systemic disease that is a constant threat to life. (Critically and/or acutely ill patients with major systemic disease)

Class 5: Moribund patients not expected to survive 24?hours, either with or without surgery.

Additional classification: "E"; emergency surgery.

regarding any intraoperative anesthetic complications. In general, the history should focus on determining whether the child is at risk for anesthetic or surgical stress as well as cardiorespiratory disease and airway compromise.

Recent URIs should be noted. A URI is an upper respiratory illness associated with fever, mucopurulent green or yellow nasal discharge, productive cough, injected sclerae, and increased mucus secretions. Clear rhinorrhea is generally not a concern. URIs can increase airway reactivity for up to 6 wk in both normal children and children with a history of reactive airway disease. URIs can also increase the risk of laryngospasm and bronchospasm, cause decreased mucociliary clearance, and increase the risk of intraoperative atelectasis and hypoxemia. It is generally recommended to avoid general anesthesia for elective cases for 4 to 6 wk after a URI. In patients with chronic sinusitis and nasal polyps, infection should be thoroughly treated before elective anesthesia.

Acute, fatal bronchospasm can occur during induction of anesthesia and endotracheal intubation for routine, minor surgery in children with asthma. Those children at particular risk for anesthetic complications with asthma are those who have (1) been admitted to the hospital within the previous year for their asthma, (2) been seen in an emergency department in the past 6 mo, (3) been admitted to an ICU, or (4) been treated with parenteral systemic steroids. The child should be free of wheezing for at least several days before surgery, even if this necessitates an increase in ß-agonists and the addition of steroids. Preoperative steroids are indicated for all children with asthma who have received or are receiving asthma therapy within the past year. Prednisone, 1?mg/kg given 24 and 12?hr before surgery, significantly decreases airway reactivity perioperatively. Active wheezing is an indication for canceling elective surgery. If wheezing cannot be controlled while an outpatient with ß-agonists, steroids, and other asthma therapy, admission for more aggressive therapy before surgery is indicated.

Bronchopulmonary dysplasia also provides significant intraoperative risks. The same applies to children with cystic fibrosis and other chronic lung diseases where every effort should be made to ensure that these children are in the best possible respiratory status before surgery. Infections should be treated and reactive airways optimally treated without evidence of wheezing.

Airway Evaluation

Because the induction of anesthesia is associated with loss of spontaneous ventilation and airway reflexes, predicting the inability to bag-and-mask ventilate or endotracheally intubate a child before anesthesia is critical. The anesthesiologist must be made aware of children with congenital anomalies that affect the airway (Box 65–5). They include micrognathia syndromes, macroglossia syndromes, and frequently children with thoracic anomalies. Congenital anomalies associated with airway compromise should be diagnosed preoperatively. Conditions that impair mouth opening (temporomandibular joint disease) should be noted. A history of wheezing or stridor may indicate postoperative airway complications and difficult intraoperative airway management.

Mediastinal Masses

Children with anterior mediastinal masses, such as lymphomas and primary mediastinal tumors, are at serious risk from airway compromise, cardiac tamponade, and vascular obstruction. Induction of general anesthesia and even mild sedation can rapidly lead to total loss of the airway with inability to ventilate the child and cardiovascular collapse. These patients often present in a semi-emergent fashion with the need for both a tissue diagnosis before initiating treatment and a surgically placed central line.

Box 65-5. Syndromes with Difficult Airways

Significant compression of vital structures can occur with seemingly mild symptoms. Tachypnea, orthopnea, wheezing, and sleep disturbances or avoidance of prone or supine positions are significant indications of serious risk. Pericardial tamponade or superior vena cava syndromes are more concerning findings. A CT scan demonstrating greater than 50% compression of the airway at the carina is an indication to prohibit general anesthesia and provide only mild sedation. Echocardiographic or CT evidence of pericardial tamponade, right ventricular compression, or compression of the pulmonary artery suggest severe risk. Biopsy under local anesthesia may be indicated. If anesthesia is required, cardiopulmonary bypass should be considered in the event that it becomes impossible to ventilate the child. In high-risk children, consideration should be given to initiating treatment with steroids, radiotherapy, and chemotherapy before obtaining a tissue diagnosis.

Down Syndrome

Children with Down syndrome are occasionally behaviorally difficult and are especially fearful of medical caregivers. Their cardiac anomalies, macroglossia, and upper airway obstruction can be challenging. Children with Down syndrome have atlantoaxial instability caused by odontoid hypoplasia and joint laxity. In younger Down syndrome children, extension of the neck, routinely used to maintain and intubate the airway, may lead to cervical dislocation and spinal cord trauma. Some anesthesiologists recommend extension and flexion lateral neck films to detect instability before anesthesia. In Down children routine caution to stabilize the cervical spine and avoid flexion and extension is wise.

Cardiovascular System

Because of the depressant effects of anesthetics and the increased demands of surgery, any compromise of myocardial function should be clearly delineated preoperatively. A preoperative ECG, echocardiogram, and cardiology consult are indicated for children with a history of heart disease. The presence of an intracardiac shunt will affect oxygenation status intraoperatively. Because of the significant impact on the oxygen supply and demand relationship caused by general anesthesia and surgical stress, obstructive lesions, such as a valvular stenosis, must also be clearly defined. A past history of cardiac dysrhythmias should be clearly understood, because inhalational anesthetics are dysrhythmogenic.

In neonates, the presence of ductus arteriosus, myocardial compromise, pulmonary edema, or congenital heart disease can significantly complicate oxygen delivery during anesthesia. Accurate diagnosis of cardiac murmurs in neonates is essential. Any cardiovascular compromise preoperatively will be worsened intraoperatively and can catastrophically complicate the perioperative course.

Anemia should be diagnosed and corrected preoperatively if possible. A hematocrit above 30% is generally acceptable for routine elective anesthesia. If there are reasons to expect significant blood loss or prolonged convalescence, anemia should be corrected preoperatively. In the emergent setting, transfusion may be required. Although lower hematocrits can be tolerated in unstressed children, the significant threat to oxygen delivery posed by anesthesia and surgery, especially if blood loss is expected, requires maintaining an adequate hemoglobin concentration perioperatively.

Evidence of coagulopathy should be sought. Easy bruising, the use of aspirin, or familial bleeding disorders should be discussed. Intraoperative hemorrhagic bleeding can be difficult to control; massive blood transfusions in the perioperative period have significant risk for morbidity and mortality. Preoperative correction of coagulopathic disorders is indicated. In neonates, assurance of vitamin K prophylaxis and adequate coagulation status is critical before any significant surgery. In neonates and critically ill children, adequate platelet count and, where indicated, coagulation factors, prothrombin time, and partial thromboplastin time should be assured.

Neurobehavioral Aspects

The child's level of interaction and understanding form a backdrop to providing safe and comfortable anesthesia for the child. The presence of seizures, significant neurologic impairment, altered level of consciousness, respiratory airway compromise secondary to neurologic disease, and neuromuscular disease should be sought and evaluated. Anticonvulsant drug metabolism is often altered perioperatively, and this may alter anticonvulsant drug levels. Anticonvulsants may also complicate the anesthetic management. Maintenance of appropriate anticonvulsant therapy postoperatively is important to avoid new seizures. Cerebrospinal fluid secretion is increased during surgery and general anesthesia. This is significant in patients suspected of elevated intracranial pressure or in children with ventriculoperitoneal shunts. In infants or older children with ventriculoperitoneal shunts, shunt patency and function should be assured before surgery.

Illness and the need for surgery or painful medical procedures are psychologically traumatic events for children and their families. Anxiety results from a host of mechanisms in the child related to loss of control, fear of the unknown, uncertainty, and separation anxiety. Children are also remarkably adept at sensing stressful signals from their parents and caregivers. Many children requiring anesthesia may develop significant levels of fear and anxiety. Most children undergoing surgery develop new-onset negative behavioral changes in the postoperative period, such as maladaptive behavioral responses that include generalized anxiety, enuresis, enhanced separation anxiety, temper tantrums, nighttime crying, and fear of strangers, doctors, and hospitals. Approximately 20% demonstrate these negative behavioral adaptations for 6 mo after surgery. Sleep quality is also altered postoperatively, resulting in further behavioral compromise.

The risk factors for postoperative behavioral changes include preoperative or induction anxiety and behaviors indicating extreme stress, as well as emergence excitation. The type of surgery may be important, with tonsillectomy and genitourinary surgery having a high incidence of postoperative behavioral changes whereas simple procedures (tympanostomy tubes) seem to be associated with fewer changes. Another risk factor is recurrent procedures, such as anesthesia for laser surgery, strabismus surgery, or repeated eye examinations, which lead to difficult behavioral changes and have a significant impact on family dynamics. The type of induction is not a factor.

Preoperative psychologic preparation programs decrease the incidence of postoperative behavioral changes, which last for up to 1 mo. Parental presence during anesthetic induction does not improve postoperative behavior. Oral midazolam (0.5?mg/kg) may decrease negative behavioral changes after surgery. Midazolam has the benefit of providing not only rapid onset anxiolysis in 10 to 20?min but very effective and rapid (10 min) amnesia.

Preoperative Preparation

The child should be in the best nutritional state, and nutritional supplementation, even hyperalimentation in chronically ill children, may be worthwhile. Catabolism is increased after surgery, and the nutritional disorders that accompany major surgery should be prepared for by optimal preoperative nutrition.

Preoperative Fasting.

Aspiration of gastric contents is a perioperative disaster and if superimposed on lung disease may be rapidly fatal. Aspiration may lead to laryngospasm and bronchospasm with hypoxemia and hypoxic ischemic encephalopathy. It may also produce intraoperative atelectasis and postoperative pneumonia. It is vital to ensure that the stomach is as empty as possible before the induction of anesthesia. Acid aspiration is less likely with an empty stomach. Preoperative fasting (NPO) guidelines are noted in Table 65–5 .

Clear, sweet liquids (Pedialyte, D_5 W) facilitate gastric emptying, help avoid hypoglycemia, and can be given up to 2?hr before anesthesia in any child. For older infants and children a fasting period of 4?hr for liquids provides optimal safety and minimal discomfort. Solids must be avoided for *at least* 8?hr before surgery. Because surgery is frequently scheduled in the morning, and for ease and clarity of understanding, the general guideline is NPO for solids after midnight. Many conditions delay gastric emptying, and prolonged periods of fasting may be required in the presence of stress, anxiety, illness, trauma, gross obesity, or biliary atresia or in children with delayed gastric emptying for other reasons.

The Full Stomach.

Because of serious complications of gastric contents aspiration, it is desirable to secure the airway as rapidly as possible after obtundation in patients at risk of having a full stomach. Gastric emptying may be delayed for up to 96?hr after an acute episode of trauma or surgical illness. Under these circumstances, induction of general anesthesia and endotracheal intubation are performed in a rapid sequence (rapid sequence induction).

Preparation is of utmost importance. All airway equipment should be available: selection of laryngoscope blades, two laryngoscope handles (in case one fails), and appropriately sized endotracheal tubes with one size above and below the appropriately sized endotracheal tube for age. Two sources of suction with two large-volume suction catheters (Yankauer suction catheters or “tonsil suckers”) should be available, because vomiting can be copious. The goal is to place an endotracheal tube through the vocal cords as rapidly as possible after the loss of airway reflexes. Because muscle relaxation with succinylcholine can take 30–45?sec, and nondepolarizing muscle relaxants 45–90?sec, the administration of sedation and muscle relaxation *concurrently* is indicated.

TABLE 65-5 -- **Preoperative Fasting Guidelines***

Time Before Surgery	Oral Intake
2 hours	Clear, sweet liquids
4 hours	Breast milk
6 hours	Infant formula, fruit juices, jello
8 hours	Solid food

** These are general guidelines and may differ among hospitals.*

Risks of rapid sequence induction include the possibility that if the airway cannot be intubated, the child is paralyzed without a protected airway and ventilation may be hazardous or impossible. Rapid sequence intubation should be performed by those who will definitely achieve rapid endotracheal intubation. Rapid sequence intubation should be avoided in patients with a history of failed oral endotracheal intubation, or with one of many syndromes (e.g., micrognathia) associated with difficult intubation. Under these circumstances, bronchoscopic awake intubation may be indicated.

Before rapid sequence induction, the child should be preoxygenated by breathing 100% oxygen for 2?min to give an extra margin of safety should intubation be difficult. The child should not be assist-ventilated either before or after the administration of drugs because this may lead to increased gastric air and actually increase the likelihood of vomiting, regurgitation, and aspiration.

A standard regimen for rapid sequence intubation includes the administration of 3–6?mg/kg of sodium thiopental or 1.5–3?mg/kg of propofol concurrently with either 0.9 to 1.2?mg/kg of rocuronium or 1.5?mg/kg of vecuronium. Immediately after the administration of sedation and muscle relaxants, the Sellick maneuver (cricoid pressure) should be performed by applying firm pressure in a posterior direction against the cricoid cartilage. This displaces the cricoid cartilage into the esophagus, forming an artificial sphincter to prevent reflux of gastroesophageal contents. Cricoid pressure should be maintained until it is certain the endotracheal tube is correctly located by direct visualization, fogging of the tube, and, in all circumstances, by positive end-tidal CO_2 .

Informed Consent.

Consent must be obtained for children undergoing anesthesia. Anesthesia consent (both permission from parents and assent from the child) follows the same guidelines as for other procedures. Whereas the benefits of a surgical procedure are intrinsic to the procedure, the risk of any procedure under anesthesia exposes the child to the additional risks of anesthetic. This particular issue is perhaps unnecessary when discussing surgery with a significant risk (cardiac or complex neurosurgical procedures); when the procedure itself has no intrinsic risks (MRI), the general anesthesia alone may be the only associated risk.

Minor risks include headache, nausea and vomiting, dental or lip trauma, delayed awakening, sore throat, and aspiration. Major risks include hypoxic ischemic encephalopathy, myocardial depression and cardiac arrest, cardiac dysrhythmias, and death (albeit extraordinarily rare). For healthy children undergoing elective surgery, the risks of a serious complication are approximately 1:100,000. In more complex and urgent situations, there is a much higher potential for anesthetic risks.

POSTOPERATIVE PAIN MANAGEMENT

The continuation of analgesia and anxiolysis should follow surgery or painful procedures (see Chapter 66). Incisional and operative pain will persist for hours to days depending on the type and location of the surgery. Complete freedom from pain is not possible. To hold forth the ability of a hospital perioperative service or physician to provide a "pain free" environment is misrepresentation and will disappoint children, families, and caregivers. Every practitioner associated with the care of children should strive to prevent, alleviate, and eradicate pain, fear, and anxiety and maximize comfort.

The combination of narcotic and non-narcotic analgesic agents and an understanding of the benefits and risks is the foundation of pain management. A judicious combination of nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 (COX-2) inhibitors, opioids, and regional analgesia has a role in postoperative pain management. Repeated evaluation is as important as the modality of pain management.

Patient-controlled analgesia (PCA), nurse-controlled analgesia, and parent-controlled analgesia are all used postoperatively (see Chapter 66). PCA provides continuous pain treatment and self-medication (as opposed to intermittent or PRN) as well as control and comfort in an otherwise personally uncontrolled circumstance. PCA provides both a background low dose infusion rate of a continuous narcotic and the opportunity to supplement analgesia with bolus doses as needed. The practitioner can determine the continuous infusion rate, the bolus dose, the bolus frequency, and the number of boluses per unit time that the patient may receive. PCA relies on the theory that patients cannot, or will not, overdose themselves because somnolence will decrease repeated self-administration. In young children, the use of the "pain button" (for pain relief) may be more difficult to ensure; however, children as young as 5 yr have successfully been able to use PCA. In older children and adolescents, PCA should be a standard modality of postoperative pain management.

The concern with nurse-controlled analgesia or parent-controlled analgesia is that an overdose is possible with complications and increased side effects. An overzealous health care provider or parent may continue to medicate the child beyond the point of pain relief and into the dose range associated with complications. Nevertheless, with careful observation and monitoring, as well as intelligent design of the continuous infusion rate, lockout periods, frequency of dosing, and bolus dose, this is a safe modality of therapy.

Regional Anesthesia

Regional anesthesia is the use of anesthetics to block the conduction of afferent neural impulses to the CNS. These can be local analgesic techniques, peripheral nerve blocks, nerve-plexus blocks, or epidural and subarachnoid (spinal) nerve blocks. They may be either by a single injection (single shot) or by continuous infusion, as is common with epidural and occasionally subarachnoid blocks. They may be used for intraoperative anesthesia and postoperative analgesia and have the potential to decrease intraoperative analgesia and anesthetic use, as well as provide postoperative pain management.

Analgesia at the site of need without central cardiorespiratory depressant effects can be valuable. Local anesthesia, with the injection of lidocaine or bupivacaine into the pain area, can provide procedural analgesia, which lasts for several hours. Infiltration of the wound site and edges of an incision decreases postoperative pain in the initial hours after surgery. This can be injected by the surgeon at the conclusion of surgery and may supplement postoperative analgesia.

Epidural analgesia is common in pediatric practice. The epidural space lies below the dura and above the pia and arachnoid membranes, an area through which all nerve roots pass. Bathing these nerve roots in local anesthetics inhibits conduction of pain impulses centrally. A single dose of epidural anesthetic may provide hours of pain relief, and a continuous infusion may provide effective pain relief for hours to days. The epidural injection of opioids can provide analgesia for 12 to 24?hr and is a potential supplement for postoperative analgesia.

A lumbar epidural is placed in the lumbar area to provide analgesia for labor and surgery below the thorax. Caudal epidural analgesia is placed through the sacral hiatus, the distal end of the spinal cord, and is the site most commonly used for anesthesia and analgesia in children and is efficacious for the provision of pelvic and lower limb anesthetic and is beneficial in orthopedic surgery and urologic surgery. A continuous infusion of bupivacaine is the most common means of providing postoperative epidural pain relief; this may be mixed with an opioid (fentanyl or preservative-free morphine). It is also possible to provide epidural PCA with a continuous infusion pump and the ability for the patient to self-medicate with bolus dosing on an as-needed basis. Epidural analgesia can also provide pain relief in patients with chronic pain or pain caused by advanced malignant conditions.

The most *serious* complications of neuraxial anesthesia include cephalad spread of blockade with respiratory depression, paralysis of respiratory muscles and, in extreme cases, brainstem analgesia and depression. The most *common* complications of neuraxial analgesia include mild discomfort; a paresthesia-like feeling of numbness and tingling; pruritus, which, if opioids are used, can occasionally be quite distressing; and occasional nausea and vomiting. Infection and epidural hematoma are extremely rare. Neuraxial opioids, especially administered intrathecally, can cause respiratory depression; their use requires postoperative monitoring. The use of neuraxial opioids often requires treatment with antipruritic as well as antiemetic drugs.

SEDATION

The same drugs that induce general anesthesia are often used to provide sedation. Sedation is the continuum between fully awake and general anesthesia (see Box 65–3). Management of sedated children requires vigilance and knowledge to ensure their safety and is guided by the same guidelines as anesthesia care (Box 65–6). For threatening and nonpainful procedures, anxiolysis or light sedation is frequently sufficient. For painful procedures the combination of sedation with analgesia that is required in children produces deep sedation.

Sedation with chloral hydrate, pentobarbital, or benzodiazepines is often adequate for nonpainful procedures. Nevertheless there can be a high failure rate and complications such as prolonged sedation (hours to overnight), ataxia, nausea and vomiting, desaturation, and occasional need for rapid intervention. The temptation to add narcotics and deepen sedation increases the risk of complications. The most rapid way to ensure safely reversible sedation is with potent anesthetic agents. The ultra–short-acting anesthetics (e.g., methohexital, remifentanil, propofol, thiopental) provide effective procedural sedation, but there is a higher likelihood of inadvertent oversedation and induction of general anesthesia. These anesthetics offer efficient and rapidly reversible procedural sedation, however, with their inherent risks. Therefore, their use requires the presence of an anesthesiologist and/or specially trained physicians.

ANESTHESIA MORTALITY AND MORBIDITY

Anesthetic mortality has decreased to 1:100,000; young age and pre-existing medical conditions present significant risk factors. The overall mortality rate for infants is approximately

Box 65-6. Systematic Approach to Sedation in Children

1. Thorough medical history anticipating underlying medical problems predisposing to sedation problems
2. Careful physical examination focused on the cardiorespiratory system and airway
3. Appropriate fasting
4. Informed consent
5. Pediatric drug dosing (milligrams per kilogram)
6. Appropriate-sized equipment
7. A separate, dedicated observer to monitor sedated patients who may have airway compromise (induced or pre-existing)
8. Documentation of vital signs and condition on a time-based record
9. An emergency backup system, code team, and crash cart
10. A fully equipped and staffed recovery area
11. Discharge criteria documenting recovery from sedation

1:40,000, whereas the risk of a complication in infants is around 4.3:1,000. Severity of illness continues to remain a risk factor, although ASAPS-1 children have a complication risk of 0.4:1,000. This rises to 16.4:1,000 in ASAPS-4–5 and is increased further by an “E” designation.

Anesthesia-related cardiac arrests occur in approximately 1.4:10,000 pediatric anesthetics. Whereas in the past, respiratory events from anesthetic overdose were the common cause of cardiac arrest, the use of pulse oximetry, anesthetic concentration monitoring, and end-tidal CO_2 has greatly reduced this risk. Most cardiac arrests (83%) occur during induction and maintenance of anesthesia, and 21% of all arrests occur during emergency surgery. Infants younger than 1 yr old account for 55% of anesthesia-related cardiac arrests; this is particularly true in the younger than 1 mo age group. Even though these special groups have elevated risk factors, it should be noted that 33% of anesthesia-related cardiac arrests occur in ASAPS-1 and ASAPS-2 patients and are more commonly related to medication-related errors than patient factors. Intraoperative cardiac arrests are commonly stated to have a good likelihood of resuscitation; however, mortality in intraoperative perianesthetic cardiac arrests is 26% in children.

Risk Reduction in Pediatric Anesthesia

Thorough physiologic assessment, attentive intraoperative management, and close perioperative monitoring are essential in minimizing risk to children. Communication among all of the child's caregivers ensures minimizing the risks associated with

anesthesia, analgesia, and sedation (Table 65–6).

Chapter 66 - Pediatric Pain Management

Brenda Bursch
Lonnie K. Zeltzer

DEVELOPMENT OF PAIN PERCEPTION

Even the smallest neonates respond to noxious stimulation with signs of stress and distress. During the 2nd trimester, afferent pathways in the human peripheral nervous system and spinal cord connect with peripheral targets and rostral projections to the thalamus and cortex develop. Neonates can even be regarded as hypersensitive to painful stimuli since reflex withdrawal is evoked by milder stimuli in neonates than in adults. Noxious stimulation in neonatal animals produces more prolonged discharges in spinal neurons than in older animals. Spinal dorsal horn neurons receive inputs from larger portions of the body surface, with greater overlap of cutaneous receptive fields. Pain inhibitory pathways become active comparatively later in development. Improved medical outcomes have been reported among neonates undergoing intensive care when efforts were undertaken to reduce painful experiences. Related research suggests that younger children may experience higher levels of distress during procedures than older children. Older children tend to display their distress less behaviorally than younger children, reinforcing the need to elicit self-reports of pain when possible.

Short-term benefits of opioid use in newborns receiving ventilatory support have been demonstrated with hemodynamic stability. Surgery in neonates receiving inadequate anesthesia evokes an outpouring of stress hormones with consequences including catabolism, immunosuppression, hemodynamic instability, and marked fluctuations in intracranial pressure.

There may also be long-term consequences of unrelieved pain in infants. More distress is observed in older infants receiving immunizations who were circumcised without anesthesia when compared with an uncircumcised group. Studies of neonatal intensive care unit (NICU) graduates have shown increased sensitivity in the heels of infants who required multiple heelsticks for blood sampling with a wider receptive field of sensitivity than the area in which the heelsticks were made. This work supports studies indicating that early significant pain exposure can sensitize the developing sensory nervous system. Preschoolers demonstrate a relationship between time in the NICU and pain complaints at age 3–4 yr. It is thought that the longer newborns are in the NICU, the more invasive procedures they might experience.

CLINICAL ASSESSMENT OF PAIN

Pain is both a sensory and emotional experience. Whenever feasible, pain is best assessed by directly asking children about the character, location, quality, duration, frequency, and intensity of their pain. Some children may not report pain because of fears such as talking to doctors, disappointing or bothering others, receiving an injection of medication, finding out they are sick, or returning to the hospital. For infants and nonverbal children, parents, pediatricians, nurses, and other caregivers are constantly challenged to interpret whether the distressed behaviors of the children represent pain, fear, hunger, or a range of other perceptions or emotions. Therapeutic trials of comfort measures (cuddling, feeding) and analgesic medications may be helpful in clarifying the situation.

Behavior and physiologic signs are useful but can be misleading. A toddler may scream and grimace during an ear examination because of fear rather than from pain. Conversely, children with inadequately relieved persistent pain from cancer, sickle cell disease, trauma, or surgery may withdraw from their surroundings and appear very quiet, leading observers to conclude falsely that they are comfortable or sedated. In these situations, increased dosing of analgesics may make the child become more, not less, interactive and alert. Similarly, neonates and young infants may close their eyes, furrow their brows, and clench their fists in response to pain. Adequate analgesia is often associated with eye opening and increased involvement in infants' surroundings. A child who is experiencing significant chronic pain may play “normally” as a way to distract attention from pain. This coping behavior is sometimes misinterpreted as evidence of the child “faking” pain at a nondistracted time.

Investigators have devised a range of behavioral distress scales for infants and young children, mostly emphasizing the patient's facial expressions, crying, and body movement. Facial expression measures appear most useful and specific in neonates. Autonomic signs can indicate pain but are nonspecific and may reflect other processes, including fever, hypoxemia, and cardiac or renal dysfunction.

Children ages 3–7 yr become increasingly articulate in describing intensity, location, and quality of pain. Pain is occasionally referred to adjacent areas; referral of hip pain to the leg or knee is not rare in this age range. There are self-report measures for children this age, using drawings, pictures of faces, or graded color intensity (Table 66–1). Children age 8 yr and older can usually use visual analog pain scales accurately. In the United States, regularly documented pain assessments are now required for children who are hospitalized and for children attending outpatient hospital clinics and emergency departments.

The measurement of pain in cognitively impaired children remains a challenge and methods are being studied to determine ways of assessing pain in this group. Understanding pain expression and experience in this population is important because behaviors may be misinterpreted as indicating that cognitively impaired children are more insensitive to pain. Children with Down syndrome may express

pain less precisely and more slowly than the general population. Pain in individuals with autism spectrum disorders may be difficult to assess because they may be both hyposensitive and hypersensitive to many different types of sensory stimuli and they may have limited communication abilities.

NONPHARMACOLOGIC APPROACHES TO PAIN MANAGEMENT

There are numerous nonpharmacologic methods that can be used to relieve pain, fear, and anxiety. These approaches have excellent safety and good effectiveness. Studies of childhood chronic headaches provide more robust evidence of effectiveness for cognitive-behavioral treatments than for pharmacologic treatment. Many of these methods are also useful because children can generalize them to new situations and benefit from an increased sense of mastery by managing their symptoms. A child who has cancer and who learns self-hypnosis to reduce distress from lumbar punctures may successfully apply this skill to other stressful situations. Clinical attention to the environment, optimal positioning, physical comforts, and choice/control should be present for every patient and family. Nonpharmacologic techniques alone may not work for some children and should not be used as an excuse for withholding appropriate analgesics.

Information should be given to children (and family members) in a developmentally and situationally appropriate manner as to what to expect with their medical condition, procedures, and treatments. Clinicians should include patients and their families

TABLE 66-1 -- **Pain Measurement Tools**

Name	Features	Age Range	Advantages	Limitations
Visual Analog Scale (VAS)	Vertical 10-cm line, subject marks on line between “no pain” (or neutral face) and “worst pain imaginable” (or sad face)	8 yr and older	Good psychometric properties; gold standard	Cannot be used in younger children or those with cognitive limitations
Faces Scale (e.g., Wong-Baker, Oucher, Bieri, McGrath scales)	Subjects compare their pain to line drawings of faces or photos of children	4 yr and older	Can use in younger ages than VAS	Choice of “no pain” face affects responses (neutral vs. smiling)
Color and other analog scales	Horizontal or vertical ruler, on which increasing intensity of red signifies more pain; pain ladder; pain thermometer; blocks	4 yr and older	Can use at younger ages than VAS; converges to VAS at older ages	Cannot be used in toddlers or those with cognitive limitations
Behavioral or combined behavioral-physiological scales (e.g., CHEOPS, OPS, FACS, NIPS)	Scoring of observed behaviors (e.g., facial expression, limb movement) ± heart rate and blood pressure	Some work for any age; some are specific age groups, including preterm infants	Can be used even for infants and nonverbal children	Nonspecific; overrates fear in toddlers and preschool children; underrates persistent pain. Some measures are convenient, others require videotaping and complex processing. Changes can occur unrelated to pain.
Autonomic measures (e.g., heart rate, blood pressure, heart rate spectral analyses)	Scores changes in heart rate, blood pressure, or measures of heart rate variability (e.g., “vagal tone”)	All ages	Can be used at all ages Useful for patients receiving mechanical ventilation	Nonspecific; changes can occur unrelated to pain
Hormonal-metabolic measures	Plasma or salivary sampling of hormones (e.g., cortisol, epinephrine)	All ages	Can be used at all ages	Nonspecific; changes can occur unrelated to pain; inconvenient; cannot provide “real-time” information

in the decision-making for pain control to ensure that the pain control option chosen is the most appropriate for the situation and to optimize adherence to treatment protocols.

Relaxation techniques promote muscle relaxation and the reduction of anxiety that often accompanies and increases pain. Controlled breathing and progressive muscle relaxation are commonly used relaxation techniques for children preschool age and older.

Distraction helps a child of any age shift attention away from pain and onto other activities. Common attention-sustainers in the environment include bubbles, music, video games, television, telephone, conversations, school, and play activities.

Hypnotherapy involves helping a child to focus on an imaginative experience that is comforting, safe, fun, or intriguing. Hypnotherapy acts to capture attention, alter sensory experiences, reduce distress, reframe pain experiences, create time distortions, help the child dissociate from the pain, and enhance feelings of mastery and self-control. This intervention is best for children of school-age or older.

Biofeedback involves controlled breathing, relaxation, or hypnotic techniques with a mechanical device that provides visual or auditory “feedback” to the child when the desired action is approximated. Common targets of change include muscle tension, peripheral skin temperature through peripheral vasodilation, or anal control through rectal muscle contraction and relaxation. Biofeedback also enhances the child's sense of mastery and control and is especially useful for the child who needs more “proof” of change than that generated through hypnotherapy alone.

Individual psychotherapy can be used to address the cognitive, behavioral, and psychological contributors to the pain and to pain behaviors. Assessing and treating maladaptive coping, anxiety, depression, learning disorders, social problem-solving deficits, communication problems, relationship issues, unresolved grief or trauma, school avoidance, or other identified problems can reduce acute distress and chronic stress load on the central nervous system, thereby reducing excessive arousal and pain.

Family education and/or psychotherapy may be employed to help family members understand the mechanisms and appropriate treatment of pain, to alter family patterns that may inadvertently exacerbate the pain, to help parents better cope with their own and their child's distress, and to develop a plan for the child's optimal self-management of symptoms and independent functioning. Cognitive behavioral family approaches have been shown to be effective for pediatric chronic pain.

Physical therapy can be very useful, especially for children with chronic musculoskeletal pain and/or who have become deconditioned from inactivity. Exercise appears to have both specific benefits related to muscle functioning and posture and more generalized benefits related to improved body image, body mechanics, sleep, and mood.

Transcutaneous electrical nerve stimulation (TENS) is quite safe and can be tried for many forms of localized pain. Children often find TENS helpful and effective; there are no randomized clinical trials of TENS for pain in children.

Acupuncture has been shown in adult studies to be effective in a variety of chronic and postoperative pain states, suggesting usefulness for pediatric myofascial pain, primary dysmenorrhea, sickle cell crisis pain, and sore throat pain. Acupuncture treatment in children can reduce both migraine frequency and intensity and increase panopioid activity that correlates with clinical improvement.

Yoga is another potentially helpful intervention for chronic pain, although studies have been conducted only in adults. Yoga typically involves a series of body poses that promotes a sense of energy, relaxation, strength, balance, and flexibility. Certain types of breathing may also accompany yoga.

Massage therapy can be very useful for children with chronic pain. Reductions in pain in children with juvenile rheumatoid arthritis and cancer and in adolescents with fibromyalgia have been noted using deep tissue massage. In addition to pain reduction and increased function, children were found to have short-term reductions in cortisol levels and improved sleep and mood.

Oral sucrose and pacifiers are effective for procedure-related pain reduction, with the combination being most effective. This approach works best with neonates, but it can be tried in infants up to 3 mo of age. Pacifiers and sucrose should not be used in lieu of analgesic medications when they are necessary and appropriate.

DEVELOPMENTAL PHARMACOLOGY

Because the pharmacokinetics and pharmacodynamics of analgesics vary with age, infants and young children respond to drugs differently from older children and adults. The elimination half-life of most analgesics is prolonged in neonates and young children because of their immature hepatic enzyme systems. Clearance of analgesics also may be variable in young infants and children. Renal blood flow, glomerular filtration, and tubular secretion increase dramatically in the first weeks and approach adult values by 3–5 mo. Renal clearance of analgesics is often greater in toddlers and preschool children than in adults, whereas premature infants tend to have reduced renal clearance of analgesics. There also are age-related differences in body composition and protein binding. Total body water as a fraction of body weight is greater in neonates. Tissues with greater perfusion such as the brain and heart account for a larger proportion of body mass in neonates than do other tissues such as muscle and fat. Because of decreased serum concentrations of albumin and a_1 -acid glycoprotein, neonates have reduced protein binding of some drugs, resulting in higher amounts of free, unbound drug. Drug dosing in infants and younger children is often extrapolated from studies in adults and older children using weight-based scaling.

Acetaminophen, Aspirin, and Nonsteroidal Anti-inflammatory Medications.

Acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) have replaced aspirin as the most commonly used antipyretics and oral nonopioid analgesics (Table 66–2).

Acetaminophen is generally a safe nonopioid analgesic and antipyretic that has the

advantage of rectal, as well as oral, route of administration. In addition, acetaminophen is not associated with the gastrointestinal effects or antiplatelet effects of aspirin and NSAIDs, making it a particularly useful drug in cancer patients. Unlike aspirin and NSAIDs, acetaminophen has little anti-inflammatory action. Toxicity of acetaminophen can occur from either large single doses or excessive cumulative dosing over days (see Chapter 704.2). Acetaminophen overdoses have been associated with fulminant hepatic failure in infants and children.

TABLE 66-2 -- **Commonly Used Nonopioid Medications**

Acetaminophen	10–15?mg/kg PO q4h 20–30?mg/kg/PR q4h 35?mg/kg/PR, q6–8h *Maximum daily dosing*: 90?mg/kg/24?hr (children) 60?mg/kg/24?hr (infants) 30–45?mg/kg/24?hr (neonates)	No anti-inflammatory action; no antiplatelet or gastric effects; toxic dosing can produce hepatic failure
Aspirin	10–15?mg/kg PO q4h *Maximum daily dosing*: 120?mg/kg/24?hr (children)	Anti-inflammatory effects; prolonged antiplatelet effects; can cause gastritis; risk of Reye syndrome
Ibuprofen	8–10?mg/kg PO q6h	Anti-inflammatory effects; reversible antiplatelet effects; can cause gastritis; extensive pediatric safety experience
Naprosyn	5–7?mg/kg PO q8–12h	Anti-inflammatory effects; reversible antiplatelet effects; can cause gastritis; more prolonged duration than that of ibuprofen
Ketorolac	Loading dose 0.5?mg/kg then 0.25–0.5?mg/kg IV q6h to a maximum of 5 days; Max. dose 30?mg loading with Max. dosing of 15?mg q6h after that	Anti-inflammatory effects; reversible antiplatelet effects; can cause gastritis; useful for short-term situations when oral dosing is not feasible
Choline magnesium salicylate	10–20?mg/kg PO q8–12h	Weak anti-inflammatory effects; lower risk of bleeding and gastritis than with conventional NSAIDs
Nortriptyline, amitriptyline	Amitriptyline at 0.2–0.5?mg/kg PO qhs, typically with maximum dose at 10–20?mg hs Nortriptyline is typically used at twice the doses described above.	Useful for neuropathic pain; facilitates sleep; can enhance opioid effect; can be useful in sickle cell pain. Rare risk of dysrhythmias; should screen for rhythm disturbances, check for normal QTc before beginning. Side effects include dry mouth, sedation, constipation, urinary retention, orthostatic hypotension, palpitations
Gabapentin (Neurontin)	Start with 100?mg bid or tid and then increase; can use up to 3600?mg/24?h, but no good studies in children to indicate minimum or maximum dosing	Is an anticonvulsant used for neuropathic pain; can be associated with sedation or headache
Thioridazine (Melleril), resperidone, thorazine, haloperidol	Thioridazine, 5–10?mg tablet or liquid concentrate; can start 10?mg PO tid and use prn qh for acute pain exacerbation, especially if nausea accompanies pain (lowest Tab is 10?mg). Resperidone can be especially useful for children with PDD spectrum or tic disorder and chronic pain; dose is 0.25?mg – 1?mg (in 0.25-mg increments) qd or bid. See PDR for other dosing.	Useful when arousal is clearly amplifying pain signaling; often used when first starting SSRI and then weaned off after on therapeutic doses of SSRI for at least 2 wk; check for normal QTc before beginning. Side effects include extrapyramidal reactions and sedation and in high doses can lower the seizure threshold in children with a seizure disorder. Diphenhydramine (Benadryl) can be used to treat or prevent dystonic reactions.
SSRIs (e.g., fluoxetine)	SSRI dosing per psychiatrist recommendation. Fluoxetine can be used in very low doses (e.g., 1?mg) for children with chronic pain and PDD spectrum disorders.	Useful for children with anxiety disorder in which arousal amplifies sensory signaling; useful in PDD spectrum disorders in very low doses; best to use in conjunction with psychiatric evaluation.
Sucrose solution via pacifier or gloved finger	*Preterm Infants (gestational age):* <28 wk: 0.2?mL swabbed into mouth; 28–32 wk: 0.2–2?mL depending on suck/swallow; >32 wk: 2?mL *Term Infants*: 1.5–2?mL PO over 2?min	Wait 2?min before starting procedure. Analgesia may last up to 8?min. The dose may be repeated once.

NSAIDs = nonsteroidal anti-inflammatory drugs; SSRI = selective serotonin reuptake inhibitor; PDD = pervasive developmental disorder.

Fever, alcohol, and dehydration may be risk factors for hepatic injury.

Aspirin is indicated for certain rheumatologic conditions and for inhibition of platelet adhesiveness, as in the treatment of Kawasaki disease. Concerns about Reye hepatic encephalopathy have resulted in a substantial decline in pediatric aspirin use during the past 20 yr (see Chapter 342).

NSAIDs are used widely for the treatment of pain and fever in children. In children with juvenile rheumatoid arthritis, ibuprofen and aspirin are equally effective but ibuprofen is associated with fewer side effects and better compliance. NSAIDs used adjunctively in surgical patients have been found to reduce opioid requirements (and opioid side effects) by as much as 35–40%. Although NSAIDs can be useful postoperatively, they should not be used as an excuse to withhold opioids from patients with unrelieved pain. Ketorolac is useful in treating moderate to severe acute pain when patients are unable to swallow oral medications.

Adverse effects of NSAIDs are rare but include gastrointestinal bleeding, renal dysfunction, and impaired hemostasis. Although the overall incidence of bleeding is very low, NSAIDs should be avoided in children who are at risk for bleeding or when surgical hemostasis is a prominent concern. Renal injury from short-term use of ibuprofen in euvolemic children is quite rare; renal risk is increased by hypovolemia or cardiac dysfunction. The safety of both ibuprofen and acetaminophen for short-term use is well established (see Table 66–2).

NSAIDs and aspirin act by inhibition of cyclooxygenase (COX), which is an enzyme that catalyzes production of prostanoids to form arachidonic acid. Cyclooxygenase has two predominant isoenzymes: a constitutively synthesized form, COX-1, found in platelets, gastric mucosa, liver, and kidneys, and an inducible form, COX-2, found in monocytes, peripheral nerve, and spinal cord and induced by injury and inflammation. Inhibition of COX-1 produces side effects, and inhibition of COX-2 produces analgesia. COX-2 inhibitors may be safer NSAIDs. Clinical trials in adults with several selective COX-2 inhibitors (e.g., rofecoxib [Vioxx] and celecoxib [Celebrex]) suggest that these agents provide analgesia similar to that obtained with NSAIDs but with a dramatic reduction in gastric, hemostatic, hepatic, and renal side effects. Thrombosis and aseptic meningitis are rare complications in adults.

Opioids.

Opioids are most frequently administered for moderate and severe pain, such as acute postoperative pain, sickle cell crisis pain, and cancer pain. Opioids can be administered by oral, rectal, oral transmucosal, transdermal, intranasal, intravenous, epidural, intrathecal, subcutaneous, and intramuscular routes. Infants and young children are often underdosed with opioids for fear of significant respiratory side effects. With proper understanding of the pharmacokinetics and pharmacodynamics of opioids, children can receive effective relief of pain and suffering with a good margin of safety (Box 66–1 and Table 66–3).

Opioids act by mimicking actions of endogenous opioid peptides in binding to receptors in the brain, brainstem, spinal cord, and peripheral nervous system. Opioids have dose-dependent respiratory depressant effects and blunt ventilatory responses to hypoxia and hypercarbia. The respiratory depressant effects of opioids can be increased with co-administration of other sedating drugs, such as benzodiazepines or barbiturates. Other common side effects can include constipation, nausea, vomiting, urinary retention, and pruritus. Optimal use of opioids requires proactive and anticipatory management of these side effects. The most common easily treatable side effect is constipation. Stool softeners and stimulant laxatives should be administered to most patients receiving opioids for more than a few days. Constipation often continues to be a problem with long-term opioid administration. Specific bowel opiate receptor antagonists may prevent this complication. Nausea sometimes subsides with long-term dosing but often requires treatment with antiemetics, such as phenothiazine, butyrophenones, antihistamines, and the new serotonin receptor antagonists. It is important for pediatricians to understand the phenomena of tolerance, dependence, withdrawal, and addiction (see Box 66–1).

Continuous opioid intravenous infusion is a safe and effective option that permits more constant plasma concentrations and clinical effects than intermittent intravenous opioid bolus dosing. One approach is to permit patients to titrate their own dosing using a patient-controlled analgesia (PCA) device. A basal continuous infusion is often also delivered. Children as young as 5–6 yr can effectively use PCA; parents or nurses can assist younger patients. When compared with children given intermittent intramuscular morphine, children using PCA reported better pain scores and satisfaction. PCA has the advantage of adjusting dosing to account for individual pharmacokinetic and pharmacodynamic variation, as well as changing pain intensity during the day. It also has the psychological advantage of promoting patient control and active coping. There may be lower overall opioid consumption and fewer side effects with use of PCA. Overdoses have been reported when well-meaning, inadequately instructed parents pushed the PCA button in medically complicated situations.

Local Anesthetics.

Local anesthetics are widely used in children for topical application, cutaneous infiltration, peripheral nerve block, epidural injection, and intraspinal punctures. Local anesthetics can be used with excellent safety and effectiveness. Excessive systemic concentrations can cause seizures, central nervous system depression, arrhythmia, or cardiac depression. Unlike opioids, there is a strict maximum dosing of local anesthetics. Pediatricians need to be aware of the need to calculate these doses and adhere to the guidelines.

Box 66-1. Practical Aspects of Prescribing Opioids

Morphine is typically regarded as a first choice for severe pain.

The right dose is the dose that relieves pain with a good margin of safety.

Dosing should be titrated and individualized. There is no “right” dose for everyone.

Dosing should be more cautious with younger infants, in patients having coexisting diseases that increase risk or impair drug clearance, and with concomitant administration of sedatives.

Anticipate and treat peripheral side effects, including constipation, nausea, and itching.

Give doses at sufficient frequency to prevent return of severe pain before the next dose.

With opioid dosing for more than a week, taper gradually to avoid withdrawal symptoms.

When converting between parenteral and oral opioid doses, use appropriate potency ratios.

Tolerance refers to decreasing effect on continued administration of drug or need for increased dosing to achieve the same effect; patients receiving opioids continually may need increasing doses to achieve analgesia; tolerance to respiratory depression develops parallel with tolerance to analgesic action; thus with the higher doses they do not develop respiratory depression

Dependence refers to the need for continued opioid dosing to prevent withdrawal symptoms (irritability, agitation, autonomic arousal, nasal congestion, piloerection, diarrhea and/or

Dependence refers to the need for continued opioid dosing to prevent withdrawal symptoms (irritability, agitation, autonomic arousal, nasal congestion, piloerection, diarrhea and/or jitteriness; and, in neonates, yawning); produced by regular or high-dose opioids for = 7 days, especially if the opioid is abruptly stopped; slow tapering may be needed

Addiction refers to psychological craving with compulsive drug-seeking behavior. Opioid underdosing does not prevent addiction and may increase drug-seeking behavior for relief of pain; good pain relief allows focus off opioids.

TABLE 66-3 -- Analgesic Initial Dosage Guidelines

Drug	Equianalgesic Doses		Usual Starting IV or SC Doses and Intervals			Usual Starting Or
	Parenteral	*Oral*	*Child < 50?kg*	*Child > 50?kg*	*Parenteral/Oral Dose Ratio*	*Child < 50?kg*
Codeine	N/R	200?mg	N/R	N/R	1:2	0.5–1?mg/kg q3–4h
Morphine	10?mg	30?mg	*Bolus*: 0.1?mg/ kg q2 – 4h	*Bolus*: 5 – 8?mg q2 – 4h	1: 3	*Immediate release*: 0.3?mg/ kg q3 – 4h

			Infusion: 0.01?mg/ kg/ hr in younger infants to 0.3?mg/ kg/ hr in older infants and children	*Infusion*: 1 – 1.5?mg/ hr		*Sustained release*: 20 – 35?kg: 10 – 15?mg q8 – 12h 35 – 50?kg: 15 – 30?mg q8 – 12h
Oxycodone	N/ A	30?mg	N/ A	N/ A	N/ A	0.1 – 0.2?mg q3 – 4h; available in liquid (1?mg/ mL)

Methadone	10?mg	20?mg	0.1?mg/ kg q4 – 8h	5 – 8?mg q4 – 8h	1: 2	0.2?mg/ kg q4 – 8h PO Available in liquid

Fentanyl	100?µg/kg (0.1?mg)	N/ A	*Bolus*: 0.5 – 1?µg/kg q1 – 2h *Infusion*: 0.5 – 1.5?µg/ kg/hr	*Bolus*: 25 – 50?µg q1 – 2h *Infusion*: 25 – 75?µg/ hr	N/ A	Transdermal patch soon available in 12.5?µg/ hr dose
Hydromorphone	1.5 – 2?mg	6 – 8?mg	*Bolus*: 0.02?mg q2 – 4h *Infusion*: 0.006?mg/ kg/ hr	*Bolus*: 1?mg q2 – 4h *Infusion*: 0.3?mg/ hr	1: 4	0.04 – 0.08?mg/ kg q3 – 4h
Meperidine (pethidine)	75?mg	300?mg	*Bolus*: 0.8 – 1?mg/ kg q2 – 3h	*Bolus*: 50 – 75?mg q2 – 3h	1: 4	2 – 3?mg/ kg q3 – 4h

Topical local anesthetic preparations have diverse uses in reducing pain, such as for suturing lacerations, intravenous catheter placements, lumbar punctures, and accessing indwelling central ports. Application of tetracaine, epinephrine (Adrenalin), and cocaine (TAC) results in good anesthesia for suturing wounds. It should not be used on mucous membranes. Cocaine is not essential; combinations of tetracaine with phenylephrine or lidocaine-epinephrine-tetracaine are equally effective. EMLA is a topical eutectic mixture of lidocaine and prilocaine that is used to anesthetize intact skin and is commonly applied for venipuncture, lumbar puncture, and other needle procedures. EMLA is safe for use in neonates. It is more effective than placebo but probably is less effective than ring block of the penis in providing analgesia for circumcision. EMLA should be used with caution for circumcision, because there was a report of redness and blistering on the penis in a study comparing dorsal penile block to EMLA. A small area should be tested first for hypersensitivity before EMLA is applied more widely.

Lidocaine is the most commonly used local anesthetic for cutaneous infiltration. Maximum safe doses of lidocaine are 5?mg/kg without epinephrine and 6?mg/kg with epinephrine. Concentrated solutions (e.g., 2%) should be avoided, because solutions as dilute as 0.3% are equally effective as 1–2% solutions, and the dilute solutions permit larger doses. For example, a 5-kg infant receiving infiltration for suturing may safely receive up to 5 × 5 = 25?mg of lidocaine. This maximum dose would be attained with either 1.25?mL of lidocaine 2%, 2.5?mL of lidocaine 1%, or 5?mL of lidocaine 0.5%.

Regional Anesthesia.

Regional anesthesia is widely used for postoperative pain relief in children after many types of surgery, such as abdominal, orthopedic, and thoracic procedures. It also can reduce the need for systemic opioids for patients with severe lung disease. Epidural analgesia and peripheral nerve blocks provide excellent analgesia and are safe even in term and preterm infants. Spinal anesthesia can be used to avoid the need for general anesthesia and for intubated infants with moderate and severe lung disease undergoing herniorrhaphy or lower extremity procedures.

SPECIFIC TYPES OF PAIN

The pharmacologic and nonpharmacologic approaches to pain management should be considered for all pain treatment plans, regardless of the type of pain. Many simple interventions designed to promote relaxation and patient control can be expected to work synergistically with pain medications for optimal relief of pain and related distress. More than one type of pain may be present in the same patient.

Brief Procedural Pain.

There is no one way to manage pain and distress for all procedures. The specific approach might vary according to the expected intensity and duration of the pain, the context and meaning of the procedure for the child and family, the coping styles and

temperaments of the child and parents, the type of procedure, and the child's pain history (especially during procedures). Interventions that reduce distress for parents and children have been associated with reductions in children's report of pain and in observations of their pain behavior. Therefore, optimal preparation might include education about the procedure, management of procedure-related expectations, development of skills designed to increase active participation and improved coping during the procedure, rehearsal of the procedure to increase mastery, and positive reinforcement for successful coping after the procedure is complete. Imagery, relaxation, and self-regulation and complementary approaches, such as massage or application of cold or heat, may be especially beneficial. Depending on the situation, it may be helpful to have the parents present if they are prepared with specific ways of comforting their child. All pain management strategies will be most effective in a quiet environment (other than entertaining auditory distractors), with calm adults, and with clear and confident instructions.

Procedures may require *analgesia* to make the procedure more comfortable, *anxiolysis* to make the procedure less terrifying, and/or *sedation* to permit a child to lie motionless. Local anesthetics, along with interventions to soothe and minimize distress, should be considered even for simple procedures, such as venipuncture. Newborn circumcisions cause significant pain during the procedure and are associated with irritability and feeding disturbances for several days. For predictably severe procedural pain, such as for bone marrow aspirations, local measures are often insufficient; systemic agents are then required. The use of anxiolytics alone does not provide analgesia and can make a child less able to communicate pain and distress.

Sedation represents a continuum of responses. The term *conscious sedation* refers to a condition in which a patient is sleepy, comfortable, and cooperative but maintains protective airway and ventilatory reflexes. The term *deep sedation* refers to a state of unarousability to voice and greater suppression of reflex responses. A dose of sedative medication that causes minimal sedation in one subject may produce complete unconsciousness and apnea in another. Careful attention to guidelines for appropriate monitoring and managing of sedation in children is imperative. For example, guidelines from the American Academy of Pediatrics recommend that sedation be conducted in a monitored setting with resuscitative drugs and equipment available and that competently trained people administer the sedatives and analgesics. One person should be assigned to monitor the child's condition and another qualified person should be present to respond to medical emergencies (Table 66–4). Most severe adverse events occur during sedations in settings outside the hospital and when these guidelines are not followed.

Operative Pain.

Morbidity and mortality can be reduced by good pain treatment. Fortunately, most postoperative pain in children can be well treated in a simple and cost-effective manner without advanced techniques. Education about the surgery and a pain management plan, development of skills designed to decrease anticipatory anxiety, and active participation in treatment planning can be helpful for some children and families. In addition to nonpharmacologic approaches, opioids are indicated to manage moderate to severe postoperative pain. The addition of other analgesics, such as acetaminophen and NSAIDs, can reduce the amount of opioid required. Pain should be controlled as quickly as possible to avoid prolonged pain, escalation of anxiety, and adverse side effects of the analgesic, such as respiratory depression. Consequently, the starting dose should be optimal and subsequent doses should be adjusted depending on patient response. Specifically, attempts should be made to avoid the administration of multiple, small, ineffective doses of analgesic. Oral routes are preferred for mild to moderate pain, and intravenous or regional routes are indicated for moderate to severe pain. Continuous or around-the-clock dosing at fixed intervals is recommended while the pain is moderate to severe. Side effects should be monitored and treated, and the potential synergistic sedative effects of analgesics, anxiolytics, antiemetics, and antihistamines require attention. Treatment of postoperative pain should not stop abruptly at the time of discharge, and a home plan for pain management should be discussed with the family if indicated.

Trauma Pain.

The management of trauma pain and distress may be given minimal attention owing to the emphasis on

---

TABLE 66-4 -- Drugs Used for Conscious Sedation in Children*

Drug	Suggested Starting Dose(s)	Comments
Midazolam	0.05?mg/kg incremental doses IV q 5–10?min up to 3–5 doses (to a maximum incremental dose of 1?mg) 0.1–0.2?mg/kg IM (maximum dose 10?mg) 0.3–0.6?mg/kg PO (maximum dose 20?mg)	Good anxiolytic Flumazenil is a reversal agent Dose more cautiously when combined with opioids
Fentanyl	0.5?µg/kg increments q 5?min up to 3–5 doses	Rapid infusion of large doses can produce chest wall rigidity Respiratory depression is amplified by co-administration of sedatives
Pentobarbital	1?mg/kg increments IV q 10?min up to 3 doses 2–4?mg/kg IM 4–6?mg/kg PO	Good sedative No analgesia Used often for radiologic procedures Can produce prolonged sedation
Chloral hydrate	25–100?mg/kg PO or PR 30–40?min before the procedure	Higher incidence of failed sedation with 25–50?mg/kg

Ketamine	0.2–0.5?mg/kg increments q 10?min × 3 1–2?mg/kg IM	Co-administration of midazolam or other benzodiazepines can reduce the risk of dysphoria or bad dreams Use should be restricted to cases managed by physicians with deep sedation qualifications
Propofol	Dosing per anesthesiologist	IV anesthetic often referred to as “milk of amnesia” Should be administered by anesthesiologist

** To ensure that patients receive optimal, safe care, it is now required in the United States that hospitals develop conscious sedation guidelines, such as those established by the American Academy of Pediatrics.These guidelines should include recommendations for withholding feeding before procedures, drug dosages, strategies to achieve patient comfort, necessary monitoring, required resuscitation equipment, and a quality improvement program for tracking outcomes and ensuring efficacy and safety.The guidelines also should specify which subgroups of patients are at increased risk and should have sedation performed by pediatric anesthesiologists.*

life-supporting, critical care interventions. Pain may be caused by the original trauma, surgical procedures, restricted movement, or underlying disease, and the presence of lines, tubes, and drains. It may be significantly exacerbated by biological and psychological post-traumatic stress responses. The thoughtful choice of analgesics, dosage, timing, and route of administration should be tailored to the individual patient, given the overall context of what is best for the patient and desired by the family. Frequent communication with the family can also serve to optimize appropriate expectations in family members, allowing them to better attend to the needs of their child. When pain is prolonged, dosages should be adjusted to compensate for physical tolerance, and weaning strategies should be used to minimize withdrawal symptoms. Attention should be paid to the child's sleep-wake cycles (because sufficient sleep will enable the child to cope better when awake) and to the child's and family's psychological response to the trauma. Parents can benefit from psychoeducation and/or consultation with a mental health provider to help them monitor their child for signs and symptoms of psychological trauma and to respond to these symptoms in a therapeutically helpful manner.

Cancer Pain.

The World Health Organization (WHO) proposed a model for analgesic therapy for cancer pain known as the “analgesic ladder” (Box 66–2). This consists of a hierarchy of oral pharmacologic interventions designed to treat pain of increasing magnitude. It presents a framework for the rational use of oral medication before application of other techniques of drug administration, because of the simplicity and demonstrated efficacy of oral medication. Opioid therapy is the preferred approach for moderate or severe pain. Nonopioid analgesics are used for mild pain, a weak opioid is added for moderate pain, and strong opioids are administered for more severe pain. Adjuvant analgesics can be added, and side effects and co-morbid symptoms are actively managed.

Although the oral route of opioid administration should be encouraged, some children are unable to take oral opioids. Intravenous infusions with a PCA are used next. Small portable infusion pumps are convenient for home use. If venous access is limited, a useful alternative is to administer opioids (especially

Box 66-2. World Health Organization Analgesic Ladder for Cancer Pain

STEP 1:

Patients who present with mild-to-moderate pain should be treated with a nonopioid.

STEP 2:

Patients who present with moderate-to-severe pain or who fail the first-step regimen should be treated with an oral opioid for moderate pain combined with a nonopioid analgesic.

STEP 3:

Patients who present with very severe pain or who fail the second-step regimen should be treated with an opioid used for severe pain with or without a nonopioid analgesic.

Medications for persistent cancer-related pain should be administered on an around-the-clock basis, with additional “as-needed” doses, because regularly scheduled dosing maintains a constant level of drug in the body and helps to prevent a recurrence of pain.

Adjuvant medications can be used to treat opioid side effects and comorbid conditions.

Adjuvant analgesics represent a diverse group of drug classes that have other indications but are analgesic in specific circumstances. Adjuvant medications should be used when indications exist at any step.

Some of the commonly used adjuvant analgesics include anticonvulsants,

circumstances. Adjuvant medications should be used when indications exist at any step.

Some of the commonly used adjuvant analgesics include anticonvulsants, antidepressants, local anesthetics, corticosteroids, antihistaminics, muscle relaxants, neuroleptics, anticholinergics (for visceral pain caused by bowel obstruction), and psychostimulants (to decrease sedation caused by opioid analgesia).

morphine or hydromorphone, not methadone or meperidine) through continuous subcutaneous infusion, with or without a bolus option. A small (e.g., 22-gauge) cannula is placed under the skin and secured on the thorax, abdomen, or thigh. Sites may be changed every 3–7 days as needed. Other alternative routes for opioids include the transdermal and oral transmucosal routes.

Pain Associated with Terminal Illnesses.

Patients with terminal illnesses, including cancer, AIDS, neurodegenerative disorders, and cystic fibrosis, need approaches to palliative care that focus on optimal quality of life. Nonpharmacologic and pharmacologic management of pain and other distressing symptoms can be one critical component of comprehensive palliative care. Differences among these conditions related to the progression of underlying illness, associated distressing symptoms, and common emotional responses should shape individual treatment plans (see Chapter 38).

More than 90% of children and adolescents dying of cancer can be made comfortable by standard escalation of opioids according to the WHO protocol. A small subgroup (5%) will have enormous opioid dose escalation to more than 100 times standard morphine infusion rates. In most of these cases, there is spread of solid tumors to the spinal cord, roots, or plexus and signs of neuropathic pain are evident.

The type(s) of pain being experienced by the patient (e.g., neuropathic, myofascial) should determine the need for adjunctive agents. Complementary measures, such as massage, hypnotherapy, or spiritual care, should also be considered in palliative care.

Chronic and Recurrent Nonmalignant Pain.

A large proportion of otherwise healthy children experience recurrent episodes or continuous nonspecific headache, chest pain, abdominal pain, or limb pains. These children, who often simply have a neurosensory pain signaling problem, may appear to be growing as expected and may show no signs suggestive of serious disease (see Chapter 158).

A thorough biopsychosocial history, review of systems, and physical examination comprise the cornerstone of diagnosis. It is also important to understand how the pain affects social functioning, school functioning and attendance, and parental behaviors toward the child. Laboratory testing and diagnostic procedures should be sparse and guided by clinical indication. Gastrointestinal barium roentgenographic studies in children with recurrent abdominal pain that appears benign from history and physical examination have a low yield. Recurrent abdominal pain may be one of a variety of functional abdominal symptoms, such as nausea, vomiting, bloating, diarrhea, or constipation, with mechanisms related to neuroenteric dysregulation rather than gastrointestinal structural or inflammatory problems. The absence of findings on radiographic or endoscopic procedures does not indicate that “the problem is fake or is psychological.”

Overall, management of chronic benign pain should emphasize nonpharmacologic approaches, rather than excessive reliance on medications in isolation. When it is concluded that a patient's pain is benign, it is very important for the pediatrician to: (1) avoid over medicalization because this can exacerbate the pain and associated disability, (2) maintain an open mind to reassessing the diagnosis if the clinical presentation changes later, and (3) understand and communicate to the family that the pain has a biologic basis (likely related to neural signaling and neurotransmitter dysregulation) and is naturally distressing the child and family. All patients and families should receive a simple explanation of pain physiology that helps them understand the importance of functional rehabilitation to normalize pain signaling, the low risk of causing further injury with systematic increases in normal functioning, and the risks associated with treating the pain as if it were acute. It is counterintuitive for most people to move a part of the body that hurts, and many patients with chronic pain develop atrophy or contractures of a painful extremity because of disuse. Additionally, associated increases in worry and anxiety may exacerbate pain and leave the body even more vulnerable to further illness, injury, and disability.

For a small subgroup of children with chronic pain, school absenteeism is a significant problem. An especially detailed assessment of possible family, cognitive, learning, peer, and anxiety or other emotional problems is indicated to ensure that a successful plan for school re-entry can be developed and implemented. Home schooling for these patients has been shown to predict poor outcome and is, therefore, not recommended as a long-term solution.

Sickle Cell Anemia (see Chapter 454.1).

Both recurrent acute severe pain and chronic persistent pain occur in some affected children. There is a marked variation in the frequency and severity of painful episodes; the majority of people with sickle cell disease come to the hospital only rarely and manage most of their symptoms at home. Successful treatment models emphasize (1) self-care and maintenance of normal activities, (2) generous dosing of opioids and NSAIDs at home by the oral route whenever possible, (3) treatment of breakthrough pain in a day-treatment program or clinic rather than in an emergency department or hospital admission, and (4) teaching of biobehavioral techniques and coping strategies before a cycle develops involving negative experiences with health care personnel. Ketorolac may reduce the need for, or the total dose of, opiates and avoid hospitalization. For severe episodes requiring inpatient treatment, intravenous opioid infusions and PCA can be used safely and effectively, although careful dose titration may be needed in many cases. Favorable effects on pain and respiratory function are possible when continuous epidural infusions are used in children at high risk for acute chest syndrome. Other strategies, like acupuncture, should also be

considered, as well as amitriptyline for enhanced sleep and opioid efficacy.

Neuropathic Pain.

Neuropathic pain is caused by abnormal excitability in the peripheral or central nervous system that may persist after an injury heals or inflammation subsides. The pain, which can be acute or chronic, is often described as burning or stabbing and may be associated with cutaneous hypersensitivity (allodynia). Neuropathic pain conditions may be responsible for more than 35% of referrals to chronic pain clinics and commonly include post-traumatic and postsurgical peripheral nerve injuries, phantom pain after amputation, pain after spinal cord injury, and pain due to metabolic neuropathies. Neuropathic pain frequently responds poorly to opioids. In adults, evidence suggests the efficacy of tricyclic antidepressants (e.g., nortriptyline, amitriptyline) and anticonvulsants (e.g., carbamazepine, gabapentin) for treatment of neuropathic pain. *Complex regional pain syndrome type I* (formerly known as *reflex sympathetic dystrophy*) is the term applied to an affected body part that has become sensitized without any specific nerve injury. Hyperalgesia can occur anywhere on the body, often in no particular neural distribution, including internal organs (e.g., stomach or esophagus). Treatment emphasizes targeted physical therapy and facilitation of functioning.

Part 9 - Human Genetics

Chapter 67 - The Molecular Basis of Genetic Disorders

H. Eugene Hoyme

THE IMPACT OF GENETICS ON THE CLINICAL PRACTICE OF PEDIATRICS

The etiology of all human disease can be considered a spectrum, from those conditions completely genetically determined to those completely environmentally determined. Most disorders fall somewhere in the middle, with the individual displaying a certain genetic propensity or resistance to a condition, on which the environment acts to determine whether or not an individual is affected.

Despite the perception that individual genetic disorders are rare, taken as a whole they account for a significant proportion of illness and disability in children. The Centers for Disease Control and Prevention has determined that birth defects and genetic disorders represent a major cause of morbidity and mortality in infancy and childhood. Twenty-five per cent to 39% of admissions to children's hospitals involve children with genetically determined or partially genetically determined disorders; 11% of all deaths in childhood are related to an underlying genetic condition.

The Human Genome Project has moved ahead at an advanced pace, and a rough draft of the human genome is now complete, spanning 90% of the sequence, with a high-resolution map anticipated to be available in 2003. The significant and surprising information that the Human Genome Project has already supplied includes the following:

1. The genome is very lumpy—some areas have functional genes packed together; other areas are composed of so-called filler DNA.
2. Humans may have fewer genes than expected, approximately 38,000. Many lower organisms have more genes than humans.
3. Human genes make more proteins per gene (three on average) than many other organisms.
4. Human proteins are more complex than those of many other organisms.
5. Dozens of human genes may be the result of horizontal transfer from bacteria.
6. The repetitive sequences in the human genome provide a fossil record dating back 800 million years.
7. A major component of the filler DNA has an important function.
8. The male mutation rate is approximately twice that of the female mutation rate.
9. Humans (including all different racial and ethnic groups) are 99.9% identical at the functional gene level, implying that there is no genetic basis for precise racial categorization. Nevertheless, various genes and genetic markers are specific for different races.

With the nature of the changes occurring at the level of DNA in genetic disorders becoming more apparent, it is possible to accurately diagnose many genetically determined birth defects and to predict the occurrence of genetic disorders of adult onset by DNA analysis. Modern ability to diagnose genetic conditions exceeds current ability to cure them; however, accurate diagnosis can and does lead to improved treatment of genetic disease such as avoidance of environmental factors that produce or exacerbate disease in the presence of the gene (cigarette smoking and alpha-1 antitrypsin deficiency). In a few instances, gene therapy can cure genetic disorders outright (Chapter 71) and as the altered proteins associated with changed genes are identified, novel methods of treating genetic disorders through replacement of the altered proteins are being developed (Chapter 75).

Pharmacogenomics is an exciting advance in the practice of clinical medicine; the synthesis of new drugs is based on genetic variations in drug response and individualized drug therapy is based on patient genotype of drug metabolizing enzymes or other drug pharmacokinetics or pharmacodynamic principles. What were previously called idiosyncratic drug reactions are now known as variations of alleles in a specific gene or totally different genes that metabolize a drug to a toxic metabolite. Allelic differences of the MDRI (multiple drug resistance gene—multidrug transporter P glycoprotein) or the many drug metabolizing genes of the cytochrome P450 system are two examples of how the same drug dose can have variable clinical effects or achieve different drug levels in patients with different alleles. Drug therapy will become more effective and less likely to be associated with adverse reactions with the application of pharmacogenomics.

THE HUMAN GENOME

The human genome has approximately 38,000 genes, which are the individual units of heredity of all traits. Reproductive or germ line cells contain one copy (N) of this genetic complement and are *haploid*, whereas somatic (non–germ line) cells contain two complete copies (2N) and are *diploid*. The genes are organized into long segments of deoxyribonucleic acid (DNA), which, during cell division, are compacted into intricate structures with proteins to form chromosomes. Each somatic cell has 46 chromosomes (22 pairs of autosomes, or non-sex chromosomes, and 1 pair of sex chromosomes [XY in a male and XX in a female]). Germ cells (eggs, sperm) contain 22 autosomes and 1 sex chromosome, for a total of 23. At fertilization, the full diploid

chromosome complement of 46 is again realized in the embryo.

The DNA molecule has three building blocks: a pentose sugar (deoxyribose), a phosphate group, and four types of bases, either purines (adenine and guanine) or pyrimidines (thymine and cytosine) (Fig. 67–1). These four bases form the alphabet of the genetic code. The basic subunit of DNA is the *nucleotide*, composed of one deoxyribose, one phosphate group, and one base. The structure of the DNA molecule is that of a double helix and is a twisted ladder, with the two sides of the ladder formed by the sugar and phosphate components, and the rungs of the ladder composed of the bases (see Fig. 67–1). Each "rung" contains one purine and one pyrimidine, binding with one another in a predictable way: "A" with "T" and "C" with "G." Different long sequences of the nucleotide bases code for different proteins. Individual triplets code for a corresponding transfer RNA, which then corresponds to its specific amino acid. Each haploid set of genes contains about 3 billion nucleotide pairs, the sum of which codes for the complicated array of human proteins.

Figure 67-1 The DNA double helix, with sugar-phosphate backbone and nitrogenous bases. (From Jorde LB, Carey JC, Bamshad MJ, et al [editors]: *Medical Genetics*, 2nd ed. St. Louis, Mosby, 1999 p. 8.)

Only a small fraction of the DNA of the cell is functionally working material during the metabolically active portion of the cell cycle; this is estimated to be 10% of the total DNA. Some of the "inactive" genetic material may be important in the regulation of gene expression or in chromosome structure and function.

Most of the genetic material is contained in the cell's nucleus. The mitochondria (the cell's energy-producing organelles) contain their own unique genome. The *mitochondrial chromosome* consists of a double-stranded circular piece of DNA, which contains 16,000 base pairs (bp) of DNA and is completely sequenced. The proteins that comprise the mitochondria may either be produced in the mitochondria (from information contained in the mitochondrial genome) or produced from information contained in the nuclear genome and transported into the organelle. All mitochondria are maternally derived (because sperm do not usually carry mitochondria into fertilized eggs); different mitochondria within a single cell with a variety of genomes reflect the maternal lines from which they descended.

THE STRUCTURE AND FUNCTION OF GENES

The basic purpose of genes is the production of structural proteins and enzymes. This occurs through a series of events, termed *transcription, processing, and translation*. DNA transmits its information by unwinding into single-stranded DNA, with one strand or the other, or both, acting as a template to be copied. If this occurs during cell replication, each of the DNA strands is copied, forming two new double-stranded daughter DNA molecules during a process termed *replication*. If the process occurs during the metabolically active portion of the cell cycle, only one strand is copied, forming a strand of messenger RNA (*mRNA*) during *transcription*. The complete DNA sequence of each gene is transcribed into mRNA, including the information used to encode amino acids (*exons*) and the noncoding sequences between exons (*introns*) (Fig. 67–2). The resultant mRNA differs from DNA in the substitution of the sugar ribose for deoxyribose and the pyrimidine uracil (U) for thymine (T). This primary transcript of mRNA is processed before leaving the nucleus, by a mechanism in which the noncoding introns are removed from the molecule and the remaining sections are spliced together to form the functional mRNA, which then migrates to the cytoplasm for translation. During *translation*, the mRNA directs the production of proteins on the ribosome by forming base pairs between three of its nucleotides, called *codons*, and three complementary nucleotides on a transfer RNA molecule (tRNA), termed *anticodons*. As the ribosome moves along the RNA sequence, codon by codon, an enzyme joins together the adjacent amino acids associated with the tRNA molecules by forming covalent peptide bonds. The structure of polypeptide chains, and, ultimately, proteins is determined by the mRNA sequence.

MUTATIONS AND THEIR CONSEQUENCES

Medical genetics is concerned with the study of human genetic variation. The basis of that variation is mutation, or change in the DNA sequence. Mutations can and do occur in every cell of the body: When they occur in somatic cells, there is a risk of cancer development; when they occur in the germ line, there is a risk that an offspring may inherit a structural or functional disability. Many mutations are benign or silent; others explain variation in the severity of a genetic disease (polymorphisms), whereas others produce serious consequences.

An awareness of some of the common types of mutations allows for a better understanding of the pathogenesis of many genetic disorders (Fig. 67–3).

If there is a change in a single base pair (a *point mutation*), one of several consequences may result: (1) there may be no change in the amino acid specified, due to the redundancy of the genetic code (a *silent mutation*); (2) a different amino acid may be specified (a *missense mutation*); or (3) a stop codon may be specified, which terminates the polypeptide change prematurely (a *nonsense mutation*). *Deletions* and *insertions* constitute a second major category of mutations; in such changes, one or more base pairs are deleted or inserted into the DNA sequence. If the deletion or insertion of base pairs is not a multiple of three, a *frameshift mutation* results. In such cases, all of the downstream codons are altered, and a markedly changed protein product results. A third common form of mutation affects *tandem repeat DNA sequences*. Some genes contain long series of identical triplet repeats, e.g., CGGCGGCGGCGGCGG, etc. For an unknown reason, in many of these genes, there is a propensity for the number of repeats to expand dramatically during meiosis or early fetal development under certain circumstances (Chapter 70). In such cases, the gene becomes inactivated (through a chemical process, methylation), resulting in marked deficiency or absence of the coded

Figure 67-2 A summary of the steps leading from DNA to proteins. Replication and transcription occur in the cell nucleus. The mRNA is then transported to the cytoplasm, where translation of the nRNA into amino acid sequences composing a protein occurs. (From Jorde LB, Carey JC, Bamshad

MJ, et al [editors]: *Medical Genetics*, 2nd ed. St. Louis, Mosby, 1999, p. 12.)

protein. Many human disorders have been identified that accompany triplet repeat expansions (Table 67–1).

Mutations usually can be classified as causing *gain of function* or *loss of function*. A gain of function mutation can result in an increase in the ability of a protein molecule to perform one or more normal functions, or, more commonly, it can result in overexpression or inappropriate expression of a gene product. Gain of function mutations most frequently produce autosomal dominant disorders (Chapter 69). Charcot-Marie-Tooth disease, type 1A, or *peroneal muscular atrophy*, the most common form of chronic peripheral neuropathy of childhood, results from duplication of the gene for peripheral myelin protein 22, resulting in overexpression of the gene product. The gain of function mutation in achondroplasia, the most common of the short-limbed skeletal dysplasias, exemplifies the enhanced function of a normal protein. Achondroplasia results from a mutation in fibroblast growth receptor 3 (FGFR3), which leads to activation of the receptor, even in the absence of fibroblast growth factor (FGF). Loss of function mutations are frequently observed in autosomal recessive disorders in which loss of 50% enzyme activity in the heterozygote continues to allow for normal function. Alternatively, loss of function mutations can result in conditions in which 50% of the gene product is insufficient for normal function (*haploinsufficiency*). Loss of function mutations can have a *dominant negative effect* when the abnormal protein product actively interferes with the function of the normal protein product.

Another category of mutations may confer a novel property on the protein synthesized, without altering the protein's normal functions. In sickle cell disease an amino acid is substituted into the hemoglobin molecule that has no effect on the ability of the protein to transport oxygen. However, unlike normal hemoglobin, under conditions of deoxygenation, sickle hemoglobin chains aggregate, forming fibers that deform the red cells. A final category of mutations results in abnormal expression of a gene over space and time. Many cancer-causing genes (oncogenes) are normal regulators of cellular proliferation during embryonic development; however, when expressed in adult life, and in cells in which they usually are not expressed, they may result in neoplasia.

Deletions can vary in their extent and, even when not visible at the cytogenetic level, can involve several genes; these are often termed microdeletions. By a variety of rearrangements, conditions referred to as *contiguous gene syndromes* may be generated. The clinician may be alerted to this possibility by an unusually diverse array of clinical features in any individual or the presence of additional features to a known condition. For example, owing to the close physical proximity of a series of genes, different deletions involving the short arm of the X chromosome can produce individuals with various combinations of the following features: ichthyosis, Kallmann syndrome, ocular albinism, mental retardation, chondrodysplasia punctata, and short stature. The individual features in each case depend on the involvement of these genes and the loss of DNA sequences in the underlying rearrangement. Many other contiguous gene syndromes have been described in humans, including Smith-Magenis, Rubinstein-Taybi, DiGeorge, and Prader-Willi syndromes.

Figure 67-3 Missense mutations (*A*) produce a single amino acid change, whereas nonsense mutations (*B*) produce a stop codon in the mRNA. Stop codons terminate translation of polypeptide. (From Jorde LB, Carey JC, Bamshad MJ, et al [editors]: *Medical Genetics*, 2nd ed. St. Louis, Mosby, 1999, p. 30.)

Rearrangements such as translocations also take place in somatic cells. The most understood are the rearrangements that occur in lymphoid cells. Some rearrangements are required for the formation of functional immunoglobulin in B cells and antigen-recognizing receptors on the T cell. Large segments of DNA, which code for the variable and the constant regions of either immunoglobulin or the T-cell receptor, are physically joined at a specific stage in the development of an immunocompetent lymphocyte. The rearrangements take place during development of the lymphoid cell lineage in humans and result in the extensive diversity of immunoglobulin and T-cell receptor molecules. It is as a result of this post–germ line DNA rearrangement that no two individuals, not even identical twins, are really identical, because mature lymphocytes from each will have undergone random DNA rearrangements at these loci.

GENOTYPE-PHENOTYPE CORRELATIONS IN GENETIC DISEASE

Genotype is defined as the genetic constitution of an individual and refers to which particular alternative version (*allele*) of a gene is present at a specific location (*locus*) on a chromosome. Phenotype is defined as the observed structural, biochemical, and physiologic characteristics of an individual, determined by the genotype, and refers to the observed structural and functional effects of a mutant allele at a specific locus. Many mutations result in predictable phenotypes. Therefore, identification of a specific mutation in an individual can often be used to predict clinical outcomes and plan appropriate treatment strategies.

TABLE 67-1 -- Mutations Showing Triplet Repeat Expansion

Condition	Repeat	Repeat Location	Pathologic Repeat Number
FRAXA	CGG	5' untranslated	200–1000
FRAXE	CGG		200–1000
FRAXF	CGG		300–500
FRA 16A	CGG		1,000–2,000
Spinal and bulbar muscular atrophy	CAG	Coding region	40–52
Huntington disease	CAG	Coding region	37–86
Spinocerebellar ataxia type I	CAG	Coding region	40–81
Spinocerebellar ataxia type II	CAG	Coding region	35–59
Spinocerebellar ataxia type 6	CAG	Coding region	21–30

Spinocerebellar ataxia type 7	CAG	Coding region	38–130
Dentatorubral-pallidoluysian atrophy	CAG	Coding region	49–75
Myotonic dystrophy	CTG	3' untranslated	50–2,000
Friedreich ataxia	GAA	1st intron	200–900

Adapted from Willems PJ: Dynamic mutations hit double figures. Nat Genet 1994;8:213.

The long QT syndrome exemplifies a disorder with predictable genotype-phenotype correlations (Chapter 428.4). Long QT syndrome (phenotype) can be caused by mutations in several genes (genotypes), which are designated LQT1, LQT2, and LQT3, all encoding cardiac ion channels. The risk for cardiac events (syncope, aborted cardiac arrest, or sudden death) is higher with mutations at the LQT1 locus (63%) or the LQT2 locus (46%) than among subjects with mutations at the LQT3 locus (18%). In addition, those with LQT1 mutations experience most of their episodes during exercise and rarely during rest or sleep; those with LQT2 and LQT3 mutations are more likely to have episodes during sleep or rest, and rarely during exercise.

Mutations in the fibrillin-1 gene associated with the Marfan syndrome represent another example of predictable genotype-phenotype correlations (Chapter 690). Marfan syndrome is characterized by the combination of skeletal, ocular, and aortic manifestations, with the most devastating outcome being aortic root dissection and sudden death. Sixty-five exons comprise the fibrillin-1 gene, and mutations have been found in almost all of these exons. The location of the mutation within the gene (genotype) may play a significant role in determining the severity of the condition (phenotype). Neonatal Marfan syndrome is caused by mutations in exons 24–27 and 31–32, whereas milder forms are caused by mutations in exons 59–65 and in exons 37 and 41.

Genotype-phenotype correlations have also been observed in cystic fibrosis (CF) (Chapter 402). CF is a chronic lung disease caused by mutations in the CF transmembrane conductance

regulator (CFTR) gene. More than 1,000 different mutations have been identified; the most common is the ?508 mutation, which accounts for 70% of all mutations and is associated with severe disease. Several mutations associated with mild disease have been identified, including 3272-26A>G, 3849+10?kb C>T, IVS8-5T, and 2789+5G>A. Patients with at least one 3272-26A>G allele and a second mutated allele (compound heterozygote) associated with severe disease are more likely to be diagnosed later, have better lung function, have lower incidence of *Pseudomonas aeruginosa* colonization, and have normal pancreatic function. Homozygotes for this mutation are not observed and may not have clinical disease. Conversely, those with

2183AA>G mutations, either homozygous or heterozygous with another CF mutation, are more likely to have early onset, severe disease. Those with this mutation tended to have severe pancreatic involvement, failure to thrive, variable lung involvement, and relatively early death.

With any given mutation, *modifier genes* for a different gene product may attenuate the mutated gene's phenotype. When sickle cell anemia is co-inherited with the gene for hereditary persistence of fetal hemoglobin, the sickle cell phenotypic expression is less severe. Modifier genes in CF may influence the development of congenital meconium ileus, or colonization with *P. aeruginosa*. Modifier genes may also affect the manifestations of Hirschsprung disease, neurofibromatosis type II, craniosynostosis, and congenital adrenal hyperplasia. The combination of genetic mutations producing glucose-6-phosphate dehydrogenase deficiency and Gilbert disease (promoter of glucuronyl transferase) exacerbates neonatal physiologic hyperbilirubinemia.

GENETIC SOURCES

The field of genetics is rapidly expanding and includes molecular basis of disease, rational approaches to disease diagnosis and management, education and counseling of families, and new ethical and social aspects of these newly discovered advances of the genetic basis of disease. To stay current, refer to one of the many constantly updated genetic based websites listed in Table 67–2 .

Chapter 68 - Molecular Diagnosis of Genetic Diseases

H. Eugene Hoyme

THE APPLICATION OF MOLECULAR GENETIC TECHNOLOGY IN CLINICAL DIAGNOSIS

Because a single gene or short segments of DNA cannot be observed microscopically, molecular genetics techniques are used to detect mutations. Information from the Human Genome Project and other advances in the field of molecular genetics have dramatically improved geneticists' ability to prenatally and postnatally diagnose genetic disorders. These

techniques have predictive capabilities for adult-onset disorders that are single-gene conditions or that are multifactorially determined (Chapter 69). Technical capabilities in genetic diagnosis may exceed the ethical framework for decisions about when, or if, such testing should be performed in children and adolescents.

MOLECULAR CYTOGENETIC TECHNIQUES

Chromosomal abnormalities, numerical and structural, are common causes of a variety of cancers and malformation syndromes (Chapter 70). Identification of these chromosomal aberrations is important for counseling families about prognosis and reproductive risks in future pregnancies. Conventional chromosome analysis is the "gold standard" in cytogenetic diagnosis, but it has limited resolution. Fluorescence-tagged assays based on cloning technologies and improved sensitivity of antibody conjugates enable the detection of subtle chromosomal changes beyond the resolution of classic cytogenetics. Such techniques expand the diagnostic capabilities for the investigation of children with mental retardation, malformations, and many other disorders.

FISH TECHNIQUES

FISH (fluorescence in situ hybridization) involves using a unique DNA sequence as a probe, searching for a target DNA sequence on the patient's sample. The locus-specific or gene-specific DNA probe is labeled with a tag (e.g., a fluorochrome), allowing its detection via fluorescence microscopy. The target DNA sequence is a chromosome preparation containing metaphase spreads and interphase (nondividing) nuclei on a microscope slide. Both the probe and target DNA are denatured, resulting in single-stranded DNA. The probe is added to the chromosome preparation and is incubated long enough to allow for the complementary DNA sequences of the probe and target to anneal or hybridize, if the target sequence is present. The DNA will only hybridize to its complementary strands and not to fragments with a different DNA sequence from other parts of the genome. The presence or absence of the bound fluorochrome-labeled probe is ascertained by examination of the sample with a fluorescent microscope. The results are usually unequivocal (Fig. 68–1).

The advantages of FISH include rapid analysis of a large number of cells, high sensitivity and specificity, and the ability to analyze uncultured and nondividing cells. Cells that were once paraffin-embedded can be analyzed. Disadvantages include the inability to provide information regarding the physical state of the DNA or chromosome segment identified. Performing FISH requires knowledge of the loci involved in an aberration as well as the appropriate probes that will detect the aberration. FISH cannot be used as a screening tool; rather it is used to answer specific questions. It is generally used either to complement classic chromosome staining methods, as a substitute for the identification of chromosomes in metaphase or interphase, or to identify specific DNA sequences known to be involved in a recognizable disease (phenotype).

Figure 68-1 Fluorescence in situ hybridization (FISH) involves denaturation of double-stranded DNA as present in metaphase chromosomes or interphase nuclei on cytogenetic slide preparations (*A*) into single-stranded DNA (*B*). The slide-bound (in situ) DNA is then renatured or reannealed in the presence of excess copies of a single-stranded, fluorochrome-labeled DNA base pair sequence or probe (*C*). The probe anneals or "hybridizes" to sites of complementary DNA sequence (*D*) within the chromosomal genome. Probe signal is visualized and imaged on the chromosome or nucleus by fluorescent microscopy. (From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: The use of molecular cytogenetic techniques in adolescent medicine practice. In Hoyme HE, Greydanus D (editors): *Genetic Disorders in Adolescents. State of the Art Reviews. Adolescent Medicine.* Philadelphia, Hanley and Belfus, 2002, pp. 305–13.)

FISH is used in prenatal diagnosis and in tumor characterization; in pediatric practice, it is usually used to detect submicroscopic chromosome deletions associated with specific malformation syndromes. Microdeletion syndromes are disorders previously thought to be of unknown etiology because the associated chromosomal deletions and rearrangements are usually not visible in conventional chromosome preparations. They are characterized by small deletions in specific chromosomal segments and can be reliably detected by FISH; examples include the Prader-Willi, Angelman, Williams, Miller-Dieker, Smith-Magenis, and velocardiofacial syndromes (Fig. 68–2). FISH has facilitated the diagnosis of these syndromes in atypical cases, especially in infants when all of the diagnostic findings are not

present. It is beneficial in adolescents and adults when the typical childhood features have changed.

SUBTELOMERIC REARRANGEMENTS

Most translocations involve the ends of chromosomes (telomeres). A large number of genes for malformation syndromes

Figure 68-2 *A*, Child with velocardiofacial syndrome (deletion 22q11.2). *B*, Child with Prader-Willi syndrome (deletion 15q11-13). *C*, Child with Angelman syndrome (deletion 15q11-13). *D*, Child with Williams syndrome (deletion 7q11.23). (From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: The use of molecular cytogenetic techniques in adolescent medicine practice. In Hoyme HE, Greydanus D (editors): *Genetic Disorders in Adolescents. State of the Art Reviews: Adolescent Medicine*. Philadelphia, Hanley and Belfus, 2002, pp. 305–13.)

are located in the regions adjacent to telomeres, the subtelomeric chromosomal regions. Screening telomeres for rearrangements is a useful way to detect submicroscopic chromosome deletions and rearrangements not detected by standard chromosome analysis. FISH screening for submicroscopic chromosome rearrangements in patients with isolated mental retardation has focused on terminal rearrangements; subtelomeric abnormalities are seen in approximately 7.5% of such patients.

COMPARATIVE GENOMIC HYBRIDIZATION

Comparative genomic hybridization (CGH) is a FISH method for genome-wide screening for differences in copy number of any DNA sequence from an individual. CGH was developed for tumor genetics (primarily solid tumors) but is used to identify the location of gains and losses of chromosome material in individuals with potential chromosome abnormalities. The technique involves mixing and hybridizing simultaneously equal amounts of differentially labeled test DNA (e.g., green fluorescence) and normal reference DNA (e.g., red fluorescence) to normal metaphase spreads. A green to red fluorescence ratio profile is produced and areas of amplification of test DNA would be detected as an excess of green fluorescence, losses as red areas reflecting deficiency of test DNA, and equal representation of test and normal DNA as yellow areas. Therefore, CGH produces a map of genome DNA sequence number. Advantages include its applicability to any tissue. The technique is not able to detect balanced chromosomal abnormalities because the DNA copy number remains the same. Chromosome copy changes smaller than 10?Mb are not resolvable, and copy number changes are not detectable if less than half of the analyzed cells contain chromosomal gains or losses.

SPECTRAL KARYOTYPING AND MULTICOLOR FISH

The limitation of CGH in detecting balanced chromosome rearrangements is overcome by multicolor painting of all chromosomes with only one hybridization. S*pectral karyotyping (SKY)* and *multicolor FISH (M-FISH)* are related molecular cytogenetic techniques that can identify balanced rearrangements. In both of these methods, each chromosome of a metaphase spread is labeled with a specific color allowing simultaneous visualization of the entire array of chromosomes. Twenty-four chromosome-painting probes and five fluorochromes are used in combination, resulting in a combinatorial labeling scheme that uniquely labels each of the 22 autosomes, and the X and Y. M-FISH requires the use of specific filter sets for each of the five fluorochromes; SKY uses spectroscopy and an interferometer to evaluate the fluorescence emission patterns. These methods permit the detection of complex rearrangements, small translocations, and marker chromosomes. Disadvantages include the inability to identify small intrachromosomal deletions or duplications and pericentric or paracentric inversions.

METHODS OF DNA ANALYSIS

Molecular cytogenetic techniques have enhanced diagnostic abilities for the detection of chromosomal deletions or duplications (containing tens or hundreds of genes). Other techniques accomplished through DNA analysis allow for detecting changes in single genes. DNA analysis is possible because DNA is a relatively stable molecule that can be isolated from any nucleated cell and stored for future potential diagnostic needs. DNA is most commonly extracted from white blood cells; other tissues include amniocytes and chorionic villi (in prenatal diagnosis), buccal cells (from cheek swabs), and fibroblasts (obtained by skin biopsy). Sampling these tissues usually yields sufficient DNA. DNA amplification techniques, such as the polymerase chain reaction (PCR), allow for amplification of the DNA from as little as one or a few cells.

SOUTHERN/NORTHERN/WESTERN BLOTTING

The *Southern blotting* technique was the first of the molecular diagnostic techniques. PCR-based methods and direct DNA sequencing have largely displaced it. In this procedure, genomic DNA is isolated from the patient and then is cut into small fragments by *restriction enzymes* (bacterial enzymes that cleave DNA at

Figure 68-3 The Southern blotting procedure for analyzing specific DNA sequences in a complex mix of different sequences, such as genomic DNA. In this example, sample 3 has a different restriction enzyme pattern for the DNA sequence detected by the probe. This variation might be due to a restriction fragment length polymorphism or to a deletion of DNA near the detected sequence. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

very specific sites). The resultant fragments are sorted by size using gel electrophoresis, transferred by “blotting” to a stable nylon filter, fixed to the filter, hybridized against a radiolabeled known gene probe, and displayed by exposure on x-ray film. Mutations can be detected by this method if they alter the length of a DNA

fragment (restriction site), which changes the resultant enzyme cleavage banding pattern of the Southern blot. This technique continues to be most useful in detecting “linkage” of a gene to a particular inherited DNA polymorphism within or around the gene in question. The gene can then be tracked through a family, even though the specific molecular defect associated with the genetic disorder cannot be identified (Fig. 68–3).

In *Northern blotting*, the pattern and abundance of messenger RNA produced by a specific gene is analyzed. RNA cannot be cleaved by the restriction enzymes; different RNA transcripts of different lengths are produced depending on the size and number of exons in a gene. Thus, mutations that alter the number and/or lengths of exons can be expected to result in detectable changes in the Northern blot. The laboratory technique is identical to the Southern blot, except that total cellular RNA or purified mRNA, rather than DNA (cleaved by restriction enzymes), is used.

In *Western blotting*, information on the size and amount of mutant protein in cell extracts from patients with specific genetic disorders is analyzed. Proteins from a cell extract are separated according to size by polyacrylamide gel electrophoresis and transferred to a membrane. The membrane is then incubated with specific antibodies to the protein. A second antibody (against the first antibody) tagged with a fluorescent dye or radioactive substance detects the protein-antibody interaction. Western blotting is used to detect the presence or absence and size of the muscle protein dystrophin in patients with X-linked muscular dystrophy.

POLYMERASE CHAIN REACTION

Although in some disorders a high proportion of mutations are the result of large deletions in DNA detectable by Southern blotting, for many conditions, the majority of the gene abnormalities are point mutations. Once a point mutation has been discovered, DNA primers can be constructed that cover the short stretch of sequence affected by the mutation. Obtaining sufficient copies of the altered DNA sequence can be a problem. The PCR technique multiplies the copies of the DNA (gene). PCR uses thermal cycling to amplify the sequence of interest and has revolutionized the detection of mutations by providing a highly sensitive method that can be performed on small samples. The

Figure 68-4 The polymerase chain reaction. By repeatedly synthesizing a region of DNA located between two DNA primers, this region of DNA is specifically and selectively amplified in an exponential fashion. Three successive rounds of amplification are shown, resulting in a total of eight copies of the targeted sequence. After 30 rounds of amplification, more than a billion copies of the sequence are created. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

technique is standardized and automated. It is relatively inexpensive; billions of copies of a specific DNA sequence can be produced in a few hours (Fig. 68–4).

DIRECT DNA SEQUENCING

Automated DNA sequencing is standard in many clinical molecular genetic laboratories and has permitted the progress of the Human Genome Project. Sequencing is particularly suitable for small genes, and for situations in which the precise mutation in a particular family is not known. All significant findings must be analyzed to determine whether the changes cause disease or are normal polymorphisms.

ETHICAL ISSUES IN GENETIC TESTING IN CHILDREN

Nothing is as personal as one's genetic material. Just because a molecular genetic test can be ordered does not mean that it should. The decision to undergo genetic testing is complicated. The decision of whether or not to perform a genetic test on a child is even more difficult, because the child cannot always participate in discussions about the testing. The ultimate decision hinges on how the results of the test will help or harm the child. The interest of the child is always foremost; thus, open discussion of the pros and cons of testing should always center on the child's interests. Molecular diagnostic tests are often used to diagnose children with malformation syndromes, mental retardation, or other disabilities wherein there is a clear benefit to the child. In other cases, the decision whether to test a child is more difficult.

The American College of Medical Genetics and the American Society of Human Genetics have suggested that the following points be fully discussed with families considering genetic testing for their children:

1. A mature minor and the parents should receive education and counseling about the genetic testing being considered, and consent should be obtained by the physician before genetic testing is done (Chapter 72). Adolescents who are 14 or 15 yr of age or older are usually considered mature minors, and assent/consent should be sought from them (Chapter 2). If a child between the ages of 7 and 14 yr is to be tested, “assent” of the child should be obtained. Assent is the child's affirmative agreement to agree with the decision of the parents.
2. The primary justification for undergoing testing should be timely medical benefit. If the test will not provide medical benefit in terms of prevention or treatment, its necessity should be questioned.
3. If medical benefit is not apparent, one must consider whether substantial psychosocial benefits to the older child or adolescent can justify testing.
4. Genetic testing should be deferred until after age 18 yr if the benefits of the testing will not become apparent until adulthood.
5. In the case of a competent adolescent, if the balance of benefits and harms is unknown, the physician should follow the decision of the adolescent regarding testing, even if it conflicts with the wishes of the parents.
6. The pediatrician should evaluate whether testing is in the best interest of the child, and, if the potential harms of testing outweigh the potential benefits, the physician should dissuade the parents from testing.

Chapter 69 - Patterns of Inheritance

H. Eugene Hoyme

GENETIC VS FAMILIAL DISORDERS

The diagnosis of a genetic disorder is based on a particular clinical pattern of symptoms and/or signs characteristic of the condition, or by laboratory confirmation of the altered gene or gene products associated with the disorder. The diagnosis is often aided by recognition of the pattern of inheritance within a family. It is important that a distinction be made between diseases that are genetic and those that are familial. A *genetic disorder* is one caused completely or partially by altered genetic material; some genetic disorders occur in multiple family members, others occur sporadically in single individuals in a family with no instances of recurrence. A *familial disorder* is one that is more common in relatives of an affected individual than in the general population; some familial disorders are genetic, and others are caused by environmental exposures (lead poisoning). Recognition of the pattern of inheritance not only assists in clinical diagnosis but also provides essential information for counseling family members about recurrence risks in future pregnancies.

THE PEDIGREE

A *pedigree* is a diagram of a family history and illustrates relationships among family members; it shows which family members are affected with specific medical conditions. Information for a three-generation pedigree should be obtained from a family being evaluated for a genetic disorder. The patient through whom the family is ascertained is called the *proband*. Individuals who share half of their genetic material with the proband are *first-degree relatives* (brothers, sisters, children, parents); those who share one fourth of their genetic material are *second degree relatives* (grandparents, grandchildren, aunts, uncles, nieces, nephews). Third and fourth degree relatives share one eighth and one sixteenth of their genetic material, respectively, with the proband (Fig. 69–1).

AUTOSOMAL DOMINANT INHERITANCE

Autosomal genes are on one of the 22 pairs of non-sex chromosomes. *Autosomal dominant disorders* are those in which a single gene in the heterozygous state is sufficient to cause the phenotype. Autosomal dominant disorders demonstrate

certain features that apply in most circumstances: (1) the disorder appears in a vertical pattern in the pedigree, with affected individuals present in every generation; (2) any child of an affected parent has a 50% risk of inheriting the disorder; (3) phenotypically normal family members do not transmit the condition to their offspring; (4) males and females are equally affected; (5) a significant proportion of cases are due to new mutation.

Figure 69-1 Symbols commonly used in pedigree charts. Although there is no uniform system of pedigree notation, the symbols used here are according to recent recommendations made by the professionals in the field of genetic counseling. (From Bennett RL, Steinhaus KA, Uhrich SB, et al: Recommendations for standardized pedigree nomenclature. *J Genet Counsel* 1995;4:267–79.)

Autosomal dominant disorders can be distinguished from X-linked conditions by the presence of male-to-male transmission in the former (Fig. 69–2). Because men transmit a Y chromosome, rather than an X chromosome, to their sons, X-linked inheritance is ruled out if a genetic disease is passed from father to son.

Autosomal dominant disorders typically show wide variation in phenotype among affected individuals within a family. This is most commonly due to *variable expressivity* of the mutated gene. The exact cause of variable expressivity is unknown, but it is most likely associated with the effects of modifying genes and the environment on the phenotype. In some families, obligate carriers of an altered gene have no apparent phenotypic manifestations of the condition. This is termed *reduced penetrance* and is an “all or none” phenomenon. In some instances when an individual appears to be nonpenetrant, the patient may actually exhibit either low-grade *somatic mosaicism* or *germ line mosaicism* for the gene. Somatic mosaicism arises in the embryo from a mutation in a somatic cell, leading to an embryo displaying a mixture of genotypes in its cells, some with and others without the mutation. Typically such individuals show fewer or no effects of the altered gene. Germ line mosaicism likewise arises postconception in the embryo and is limited to those cells that are precursors

Figure 69-2 Pedigree showing typical inheritance of a form of progressive sensorineural deafness (DFNA1) inherited as an autosomal dominant trait. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

of eggs or sperm. Germ line mosaicism has been commonly observed in conditions such as osteogenesis imperfecta and the craniosynostosis syndromes: Apert and Crouzon syndromes.

Because only one dose of an altered gene is necessary for phenotypic expression in autosomal dominant disorders, the condition is often the consequence of a new mutation in many affected individuals. The more severe the disorder, the higher the percentage of cases resulting from de novo mutations of the gene; in severe disorders, reduced reproductive capacity limits transmission of the gene from generation to generation. Older paternal age (>40 yr) is observed in some cases of new mutation.

Neurofibromatosis I: A Typical Autosomal Dominant Disorder

Neurofibromatosis is a heterogeneous disorder with two distinct phenotypes: neurofibromatosis 1 (NF1) and neurofibromatosis 2 (NF2). Both conditions are genetically determined, inherited as autosomal dominant traits. NF2 (also known as bilateral acoustic neurofibromatosis) is the less common of the two and is mapped to a locus distinct from NF1.

Neurofibromatosis (NF1) is a common neurocutaneous disorder, with an estimated prevalence of 1 in 3,000 live births (Chapter 589.1). It is due to a mutation in the neurofibromin gene (*NF1*) on the long arm of chromosome 17. Half the patients have NF1 from a new gene mutation, making the mutation rate of the neurofibromin gene among the highest in humans. The offspring of an affected individual have a 50% risk of inheriting the altered *NF1* gene (Fig. 69–3). DNA-based testing for the *NF1* gene is available but is rarely needed for diagnosis or prenatal diagnosis.

Multiple café au lait spots and associated cutaneous findings of neurofibromas, plexiform neurofibromas, and axillary or inguinal freckling characterize NF1. Other manifestations include an increased risk for optic glioma, osseous lesions, and learning disability. As with many autosomal dominant disorders, there is widely variable expressivity in affected patients. The diagnosis of NF1 is based on clinical findings, and consensus diagnostic criteria. The National Institutes of Health diagnostic criteria for NF1 are met in an individual with two or more of the following features:

- Six or more café au lait macules >5?mm in greatest diameter in prepubertal individuals and >15?mm in greatest diameter in postpubertal individuals
- Two or more neurofibromas of any type or one plexiform neurofibroma
- Freckling in the axillary or inguinal regions
- Optic glioma
- Two or more Lisch nodules (iris hamartomas)
- A distinctive osseous lesion such as sphenoid dysplasia or thinning of long bone cortex with or without pseudarthrosis
- A first-degree relative (parent, sibling, or offspring) with NF1 as defined by the above criteria

These criteria are highly specific and sensitive in adults with NF1 but may be inconclusive in young infants. The diagnosis can be confirmed clinically by age 4 yr in nearly all cases. A finding of multiple café au lait spots in a young infant is insufficient to make the diagnosis of NF1 (without a positive family history);

Figure 69-3 Pedigree of family with neurofibromatosis, type 1, apparently originating as a new mutation in the proband (*arrow*). (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

most will later meet the diagnostic criteria for NF1 and, therefore, should be followed

up expectantly. The American Academy of Pediatrics has published guidelines for the health supervision of affected children. These include yearly physical assessment, including blood pressure, scoliosis screening, ophthalmology examination, developmental screening, and neurologic examination. Baseline imaging studies of the cranium are usually not warranted; if there is any suggestion of central nervous system involvement, imaging and referrals should be undertaken immediately.

AUTOSOMAL RECESSIVE INHERITANCE

Autosomal recessive disorders are those in which two copies of the mutant gene in the homozygous state are necessary to cause the phenotype. This implies that both parents of an affected individual are heterozygous carriers of the gene. In general, autosomal recessive disorders are less common than autosomal dominant conditions, although the carrier frequency of many such genes in the heterozygous state may be common in the general population.

The pedigree illustrating this pattern of inheritance (Fig. 69–4) shows the following characteristics: The child of two heterozygous parents has a 25% chance of being homozygous (i.e., a 1 in 2 chance of inheriting the mutant gene from each parent: 1/2 × 1/2 = 1/4); males and females are affected with equal frequency; the affected individuals are almost always born in only one generation of the family; the children of the affected (homozygous) person are all heterozygotes; the children of a homozygote can be affected only if the spouse is a heterozygote, which is a rare event because of the low incidence of most adverse recessive genes in the general population.

If the frequency of an autosomal recessive disease is known, the frequency of the heterozygote or carrier state can be calculated from the Hardy Weinberg formula

in which p is the frequency of one of a pair of alleles and q is the frequency of the other. For example, if the frequency of cystic fibrosis among white Americans is 1 in 2,500 (p^2), then the frequency of the heterozygote (2?pq) can be calculated; if p^2 = 1/2,500, then p = 1/50 and q = 49/50; 2pq = 2 × 1/50 × 49/50, or approximately 1/25 (or 3.92%).

Every human probably has several rare, harmful, recessive genes. Because these mutant genes are frequently not identifiable by laboratory tests, the heterozygous adult usually learns about his or her harmful recessive genes after the birth of a homozygous (and therefore affected) child. Related parents are much more likely to be heterozygous for the same harmful recessive genes because they have a common ancestor.

Autosomal recessive disorders demonstrate certain features that apply in most circumstances: (1) autosomal recessive disorders

Figure 69-4 Autosomal recessive inheritance.

display a horizontal pattern in pedigrees (if more than one member of a family is affected, they are typically siblings of the proband, not parents or other relatives); (2) males and females are equally affected; (3) parents of an affected child are asymptomatic heterozygous carriers of the gene; (4) the recurrence risk for siblings of an affected child is 25%.

The chance that any two parents carry an identical mutant allele is increased if the couple is consanguineous (Fig. 69–5). *Consanguinity* is defined as relationship by descent from a common ancestor. Consanguinity between parents of a child with a suspected genetic disorder implies (but does not prove) autosomal recessive inheritance. Although consanguineous unions are uncommon in Western society, in some parts of the world (Southern India, Japan, and the Middle East) they are common. The risk for the offspring of a first cousin marriage (6–8%) is about double the risk in the general population (3–4%). There are some genetic isolates (small populations separated because of geography, religion, culture, or language) in which rare recessive disorders are more common than in the general population. Even though consanguinity may not be increased in these populations, because of limited mate choice, the chance of a couple from an isolated genetic region having a child with an autosomal recessive condition may be as high as that observed in first cousin marriages. Screening programs have been developed in such groups to detect heterozygotes at risk for having affected children. A variety of autosomal recessive conditions are more common among Ashkenazi Jews than in the general population. National practice guidelines recommend screening asymptomatic Ashkenazi Jews for the neurodegenerative disorders Tay Sachs disease (GM_2 gangliosidosis) and Canavan disease (aspartoacylase deficiency); carrier screening for other disorders (Fanconi anemia, Gaucher disease, cystic fibrosis,

Figure 69-5 Pedigree in which parental consanguinity suggests autosomal recessive inheritance. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

familial dysautonomia, nesidioblastosis) is also being considered for inclusion in this population.

The prevalence of carriers of certain autosomal recessive genes in some larger populations is unusually high. In such cases, *heterozygote advantage* is postulated. The carrier frequencies of sickle cell disease in the African population and of cystic fibrosis in the northern European population are much higher than would be expected from new mutations. It is possible that heterozygous carriers have had an advantage in terms of survival and reproduction over noncarriers. In sickle cell disease, the carrier state may confer some resistance to malaria; in cystic fibrosis, the carrier state has been postulated to confer resistance to cholera and enteropathogenic *Escherichia coli* infections. Population-based carrier screening for cystic fibrosis is now recommended for individuals of northern European and Ashkenazi Jewish background; population-based screening for sickle cell disease is recommended for individuals of African background.

X-LINKED INHERITANCE

X-linked disorders are those associated with altered genes on the X chromosome. Most X-linked disorders demonstrate a recessive pattern of inheritance, although a few X-linked dominant conditions have been well described. The characteristics of X-linked conditions differ significantly from autosomal disorders. Because females inherit two copies of the X chromosome, they may be heterozygous or rarely homozygous for any allele at a particular locus; thus, in females, X-linked genes behave like autosomal genes. Because of X-inactivation (a random process occurring early in female embryogenesis), only one X chromosome is active in each cell. Therefore, a female who is heterozygous for a mutant X-linked allele will produce 50% of the normal amount of gene product, similar to a heterozygote for an autosomal recessive condition. This is usually sufficient for a normal phenotype. Because a male inherits only one X chromosome, he is *hemizygous* for all of the genes present at all loci along the chromosome, and all of the genes are expressed. If a male inherits an altered X-linked gene, he will express the condition, because the Y chromosome contains no normal allele to compensate for the mutated gene.

X-LINKED RECESSIVE INHERITANCE

Certain features apply in most circumstances of X-linked recessive inheritance: (1) the incidence of the condition is much higher in males than in females; (2) heterozygous female carriers are usually unaffected; (3) the gene is transferred from an affected man to all of his daughters, and any of his daughters' sons has a 50% chance of inheriting the gene; (4) the gene is never transmitted from father to son; (5) the gene may be transmitted through a series of carrier females, in which case all affected males are related through the carrier females; (6) a significant proportion of sporadic cases are a consequence of new gene mutations (Fig. 69–6).

There are circumstances when females may be affected with X-linked recessive conditions. If both parents carry an X-linked recessive allele, a girl can inherit the altered gene in a homozygous state. However, because most X-linked recessive disorders are rare, this circumstance would be unlikely (except in the case of consanguinity). If a girl has Turner syndrome, accompanying a 45,X chromosome complement, she is hemizygous for all genes on the X chromosome and expresses all genes at all loci, similar to a male. Thus, X-linked recessive disorders are more common in females with Turner syndrome. Finally, because X inactivation is random, it follows a normal distribution in the embryo. Therefore, there will be a few females who by chance have one or the other of their X chromosomes nearly completely inactivated. This *skewed X inactivation pattern* is frequently observed in females who manifest X-linked recessive disorders.

Hemophilia A: A Typical X-Linked Recessive Disorder

Hemophilia A (classic hemophilia) is characterized by a deficiency in coagulation factor VIII, which results in prolonged blood oozing after injuries, tooth extractions, or surgery, renewed bleeding after initial bleeding has stopped, and delayed bleeding (Chapter 468.1). The age of diagnosis and frequency of bleeding episodes are related to the factor VIII clotting activity; mild and severe cases exist. Severe cases are usually diagnosed in infancy; mild cases may not be diagnosed until adolescence or adulthood. Because of skewed X-chromosome inactivation, approximately 10% of carrier females are at risk for mild bleeding.

The diagnosis of hemophilia A is established by documenting low factor VIII clotting activity in the presence of a normal von Willebrand factor (vWF) level. Molecular genetic testing of the factor VIII (*F8*) gene (located on the long arm of the X chromosome, at Xq28) identifies disease-causing mutations in up to 90% of patients with severe hemophilia A and about 80–95% of patients with mild to moderately severe hemophilia A. Such testing is not necessary but is available. Molecular genetic testing is used for genetic counseling of at-risk family members and occasionally in diagnosing mild cases.

Hemophilia A is inherited in an X-linked recessive manner. The risk to siblings of a proband depends on the carrier status of the mother. Carrier females have a 50% chance of transmitting the *F8* mutation in each pregnancy. Sons who inherit the mutation will be affected; daughters who inherit the mutation are carriers. Affected males transmit the mutation to all their daughters and none of their sons. Prenatal testing is possible and is more sensitive if the *F8* disease-causing mutation has been identified in a family member or if informative linked markers are known.

Figure 69-6 Pedigree pattern demonstrating an X-linked recessive disorder such as hemophilia A, transmitted from an affected male through females to an affected grandson and great grandson. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

X-LINKED DOMINANT INHERITANCE

An X-linked disorder is described as dominant if the condition is regularly expressed in the heterozygous female carriers. Characteristics of X-linked dominant inheritance include (1) all of the daughters and none of the sons of an affected man have the condition; (2) both male and female offspring of affected females have a 50% risk of inheriting the condition; (3) for rare X-linked dominant conditions, affected females are about twice as common as affected males, but affected females typically have milder (although variable) manifestations of the phenotype (Fig. 69–7).

There are only a few X-linked dominant disorders. One condition is *hypophosphatemic rickets* (vitamin D–resistant rickets); although both males and females express the condition, males are more severely affected than females. Some rare X-linked disorders occur nearly exclusively in women, because the hemizygous state of the condition is lethal in the male embryo. *Incontinentia pigmenti* (IP) is one such disorder that affects the skin, hair, teeth, and nails (Chapter 642). The skin lesions evolve through characteristic stages from blistering in infancy, to a wart-like rash (for several months), and finally, swirling hyperpigmentation and hypopigmentation. Alopecia, hypodontia, abnormal tooth shape, and dystrophic nails are observed. Some patients have retinal vascular abnormalities predisposing to retinal detachment in early childhood, and cognitive delays or mental retardation are occasionally seen (Fig. 69–8). The diagnosis of IP is established by clinical findings and occasionally by corroborative skin biopsy. Molecular genetic testing of the *IKBKG* gene (chromosomal locus Xq28) reveals disease-causing mutation in about

80% of probands. Such testing is available clinically. Females with IP have skewed X-chromosome inactivation; testing for this can be used to support the diagnosis. Affected women have a 50% risk of transmitting the mutant *IKBKG* allele; affected male conceptuses abort. The expected ratio of liveborn children is 33% unaffected females; 33% affected females; 33% unaffected males.

MULTIFACTORIAL INHERITANCE

Most of the common isolated congenital anomalies (e.g., neural tube defects, cleft lip, cleft lip with cleft palate, isolated cleft palate, club feet, and cardiac septal defects) and many of the common disorders of adult life (e.g., diabetes mellitus, hypertension, stroke, coronary artery disease, and schizophrenia) are inherited in a multifactorial manner. *Multifactorially determined disorders* are those that are the product of multiple genetic and environmental factors. The genetic factors predisposing to these disorders are heterogeneous and largely unknown. The *multifactorial model* envisions liability genes predisposing to a particular anomaly or disease as a normal distribution (Fig. 69–9). Theoretically, a point exists on the curve (*threshold of liability*), below which individuals are unaffected and above which the condition is manifest. The threshold can be moved to the left or the right by the environment. For example, in the case of neural

Figure 69-7 Pedigree pattern demonstrating X-linked dominant inheritance. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

tube defects, certain teratogens (e.g., valproate) can move the threshold to the left, allowing a child to be affected with a smaller genetic predisposition. Alternatively, the threshold can be moved to the right by maternal folic acid supplementation prior to conception, exerting a protective effect in an embryo with a susceptible genetic background.

Characteristics of multifactorially determined disorders include the following:

1. There is a similar rate of recurrence (typically 3–5%) among all first-degree relatives (parents, siblings, and offspring of the affected child). However, it is unusual to find a substantial increase in risk for relatives related more distantly than second degree to the index case.
2. The risk of recurrence is related to the incidence of the disease.
3. Some disorders have a sex predilection, as indicated by an unequal male:female incidence. Pyloric stenosis is more common in males, whereas congenital dislocation of the hips is more common in females. Where there is an altered sex ratio, the risk is higher for the relatives of an index case in the less commonly affected sex. The risk to the son of an affected female with infantile pyloric stenosis is 18% compared with the 5% risk for the son of an affected male. The female has passed on a greater genetic susceptibility to her offspring.
4. The likelihood that both identical twins will be affected with the same malformation is less than 100% but much greater than the chance that both members of a nonidentical twin pair will be affected. The frequency of concordance for identical twins ranges from 21% to 63%. This distribution contrasts with that of mendelian inheritance, in which identical twins always share a disorder due to a single mutant gene.
5. The risk of recurrence is increased when multiple family members are affected; these instances are often the most problematic for distinguishing a multifactorial from a mendelian etiology. A simple example is that the risk of recurrence for unilateral cleft lip and palate is 4% for a couple with one affected child and increases to 9% with two affected children.
6. The risk of recurrence may be greater when the disorder is more severe. The infant who has long-segment Hirschsprung disease has a greater chance of having an affected sibling than the infant who has short-segment Hirschsprung disease.

NONTRADITIONAL PATTERNS OF INHERITANCE

Genetic disorders are sometimes inherited in ways that do not follow the usual patterns of dominant, recessive, X-linked, or multifactorial inheritance. These atypical patterns of inheritance sometimes involve specific diseases and in other instances may apply to any hereditary disorder.

Certain diseases display an atypical mode of inheritance because they result from mutations in mitochondrial DNA (mtDNA). Mitochondria contain small circular chromosomes that encode 13 proteins that function in the respiratory chain of the organelle. Mutations of the mitochondrial genome (which are often deletions) can produce specific diseases. Abnormalities in these disorders are typically seen in one or more specific organs: the brain, eye, and skeletal muscle. Examples are *Kearns-Sayre syndrome* and *Leber hereditary optic neuropathy*. Because mitochondria are inherited virtually exclusively from the mother, these conditions are passed from mother to offspring, without regard to sex of the latter (thus differing from X-linked recessive inheritance). Because the mitochondria of an individual constitute a heterogeneous mixture of genotypes both within and between cells, the mitochondrial complement passed in the egg is often not representative of the total mitochondrial population of the mother. mtDNA mutations produce disease only in the presence of many mutated mitochondria: 50–60% for single large deletions and 80–90% for point mutations. Mitochondria populations are not equally distributed to all tissues. Some mitochondria demonstrate a replicative

Figure 69-8 Typical linear erythema and blistering in a female infant with incontinentia pigmenti. As the child grows older, the skin lesions will become flattened, pigmented streaks. (Photograph courtesy of Virginia Sybert, University of Washington, Seattle, WA. From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

Figure 69-9 A liability distribution for a multifactorial disease in a population. To be affected with the disease, an individual must exceed the threshold on the liability distribution. This figure shows two thresholds, a lower one for males and a higher one for females (as in pyloric stenosis).

advantage over other inherited populations of mitochondria. Thus, there is a great variability in symptoms within a family, and the observed inheritance may be more complex than a simple maternal pattern. Although uncommon, mtDNA mutations

(deletions) may occur by paternal inheritance. The finding of a myopathy or neurologic disease that seems to come from the mother's side should alert the clinician to the possibility of a mitochondrial etiology. Traditionally, sperm mitochondria undergo destruction by nuclear encoded proteins. For paternal mtDNA inheritance, the father's mitochondria may have a replicative advantage or the destruction of mitochondria may be attenuated.

Another type of nontraditional inheritance is the result of a phenomenon known as *genomic imprinting* (Chapter 70). This takes place in the germ line and results in certain regions of the genome being inherited differently, depending on the parent of origin. Specifically, genes in the relevant region are functionally inactivated (imprinted) during gamete formation and remain inactive in the resulting zygote. The genes imprinted in the two parental germ lines are mutually exclusive sets; otherwise, the offspring would have no active copies of the genes. This imprinting phenomenon leads to clinical consequences in the case of *Prader-Willi syndrome* (PWS). About two thirds of these patients have de novo microdeletions of chromosome 15, and the deletions always occur on the paternally derived chromosome. Similar deletions inherited on the maternal chromosome 15 do not result in PWS and, in fact, give rise to a different disorder, *Angelman syndrome*. In PWS, the relevant gene or genes are silenced on the maternal chromosome 15, so that a deletion on the paternal chromosome leaves the individual with no active alleles (the reverse is true for Angelman patients, in whom silencing of critical paternal genes with deletion of maternal loci results in the absence of active alleles). Most PWS patients who do not have deletions are found to have inherited two copies of their maternal chromosome 15 and are missing the paternal chromosome. Because both maternal chromosomes are silenced in the critical region, these individuals, like the deletion patients, have no active copies of the critical genes. The situation of inheriting both homologous chromosomes from a single parent is called *uniparental disomy*. A number of individuals with abnormal phenotypes have been observed to have uniparental disomy for particular chromosome regions. Thus, at least for certain regions of the genome, it is necessary to have sequences

from each parent, so that one can express at least one copy of the relevant genes.

Chapter 70 - Chromosomal Clinical Abnormalities

Judith G. Hall

The chromosomes are made up of DNA and other protein complexes and contain most of the genetic information that is passed from one generation to the next. Chromosomes are normally visualized through the microscope only when they are in a contracted state as they go through cell division. Chromosome studies are important because abnormal chromosome number (e.g., trisomy 13) and abnormal chromosomal arrangements (e.g., microdeletion 15q) may lead to multiple congenital anomalies. Improved culture and staining techniques allow the description of a large number of chromosomal abnormalities associated with specific disorders, and techniques of molecular genetics facilitate the identification of the specific position of genes (FISH—fluorescent in situ hybridization) as well as their presence or absence along the chromosomes (see Chapters 67 and 68).

Cytogeneticists arrange chromosomes by size in pairs—the largest being chromosome 1 and the smallest, chromosome 22 (although chromosome 21 has been found to actually be the smallest)—and then the sex chromosomes X and Y. The X chromosome is a large submetacentric chromosome, and the Y chromosome is a small acrocentric chromosome (Fig. 70–1). The position of the centromere in regard to the chromosome arms is another distinguishing feature of each chromosome (Fig. 70–2). The short arm of a chromosome is referred to as p (for petite) and the long arm as q (for the next letter in the alphabet).

Nomenclature.

A karyotype is the designation for the visual display of chromosomes and is obtained after the chromosomes are arrested during cell division in prophase and are photographed and arranged according to size. The visual display can be produced by computer. A description of a karyotype consists of three parts: (1) the number of chromosomes, (2) the sex chromosome constitution, and (3) any abnormalities found. The normal karyotype is 46, XX for females and 46, XY for males. If an abnormality is found, it is noted after the sex chromosome constitution. For example, in the case of a female with cridu-chat syndrome in which a piece of the short arm of the chromosome 5 is missing, the karyotype would be 46, XX, 5p-. In a male with Down syndrome in which there is an extra chromosome

Figure 70-1 Karyotype of normal male with chromosomes in late prophase. The chromosomes are longer, and a greater number of bands are seen than when chromosomes are photographed at metaphase.

Figure 70-2 *A*, Centromere position determining the three types of chromosomes seen in the normal human karyotype—metacentric, submetacentric, and acrocentric. *B*, Morphologic landmarks useful in chromosome identification.

21, the karyotype is 47, XY, +21. In the case of translocations, the chromosomes involved are written in brackets preceded by a “t” as in 45, XX, t(13q14q), indicating a female carrier of a translocation between the long arms of chromosomes 13 and 14. If the chromosome breaks are along an arm of a chromosome, the band position at which the break occurred is also indicated in the brackets, for example, 45, XY, t(13q2.1-14q1.3), indicating a male carrier of a translocation within the long arms of chromosome 13 and 14.

Cell Division.

There are two types of cell division: mitosis and meiosis. *Mitosis* is the type of cell division that occurs in most cells of the body. It is during mitosis, specifically the prophase stage of mitosis, that chromosomes are visible and easy to identify for karyotyping. In mitosis, two genetically identical daughter cells are produced from a single parent cell. Before cell division, DNA replication has occurred so that there is a doubled amount of DNA and the chromosomes contain two identical sister chromatids. Mitosis is divided into stages. *Prophase* is characterized by spiraling of the chromosome threads into coils to form microscopically identifiable chromosomes; the nuclear membrane and the nucleolus disappear and the mitotic spindle forms. In *metaphase*, the chromosomes condense and are clearly visible as distinct structures. The centromeres of the chromosomes attach to the microtubules of the mitotic spindle and the chromosomes align at the middle of the cell along the spindle. *Anaphase* is characterized by division of the chromosomes along their longitudinal axis to form two daughter chromatids and migration of each chromatid of the pair to opposite poles of the cell. *Telophase*, which completes mitosis, is characterized by reconstitution of the nuclear membrane and nucleolus, duplication of the centrioles, and cytoplasmic cleavage to form the two daughter cells.

Meiosis is the form of cell division that occurs to produce germ cells or gametes (sperm and egg). A diploid cell (with two sets or 46 chromosomes) divides to form haploid cells (with one set or 23 chromosomes). Meiosis is divided into two parts: meiosis I and meiosis II. DNA replication occurs before meiosis I. In male meiosis, the germ cell begins division with two times the normal cellular amount of DNA. In *meiosis I*, each daughter cell gets one of the duplicated chromosomes of each pair. At the beginning of *meiosis II*, each cell contains 23 chromosomes, each with a duplicated pair of chromatids. In meiosis II, the duplicated pair separate and each daughter cell ends up with one of each of the 23 chromosomes, that is, there are four daughter cells, each with a haploid (half the normal number) set of chromosomes. In female meiosis, rather than going through cell divisions during meiosis I, one diploid set of chromosomes condenses and forms a polar body, and

during meiosis II, one of the haploid sets of chromosomes condenses and forms the second polar body, resulting in one egg with a haploid (half the normal number) set of chromosomes and two polar bodies that contain three sets of chromosomes.

There is exchange between chromosomes (crossing over of chromosome segments) during meiosis, leading to new alignment and combination of genes. Two common errors of cell division occur during meiosis that result in abnormal numbers of chromosomes and chromosomal anomalies. The first is *nondisjunction*, in which two chromosomes fail to separate and thus migrate together into one of the new cells, producing one cell with two copies of the chromosome and one cell with no copy. The second is *anaphase lag*, in which a chromatid is lost because it fails to move quickly enough during anaphase to become incorporated into one of the new daughter cells (Fig. 70–3).

Methodology.

Chromosome studies can be obtained from any dividing nucleated cell. The techniques for visualization require condensation of chromatin material that occurs at cell division. Cytogenetic studies are usually performed on blood lymphocytes, but cytogenetic studies of fibroblasts must be considered if there is a suspicion of mosaicism. Chromosome studies for prenatal diagnosis are performed with cells obtained from amniotic fluid, chorionic villi tissue, fetal blood, or in preimplantation prenatal diagnosis by analysis of a blastomere.

Karyotyping refers to the systematic arrangement from a photograph or by a computer of previously stained and banded chromosomes of a single cell by pairs (see Fig. 70–1). The cells are cultured, arrested in mitosis during metaphase, and then fixed and stained. If finer details are necessary, prophase chromosomes may be examined. Because prophase chromosomes are longer and less condensed, they show 600–1,200 bands, compared with metaphase chromosomes, in which only 400–600 bands are usually visible. Trypsin-Giemsa staining gives G banding. Quinacrine gives the Q (fluorescent) banding. Special stains are used to demonstrate centromeres.

In situ hybridization is used to identify the presence or absence of specific DNA sequences on a chromosome spread. A molecular probe is used to recognize and attach to homologous DNA sequences on the chromosome spread, identifying a specific chromosome, chromosome segment, or DNA sequence. If fluorescent probes are used, the technique is called FISH (see Chapters 67 and 68).

Comparative *genomic hybridization* is a molecular cytogenetic technique that allows simultaneous enumeration of every chromosome. It involves the isolation of test DNA from a single cell (multiplied by polymerase chain reaction) or multiple cells from the test individual and comparison with DNA from a normal reference individual. The test DNA is labeled in a different way (green fluorochrome) from the reference DNA (red fluorochrome). The test and reference DNA are simultaneously hybridized to normal chromosomes. The fluorescent images reveal ratios of green to red and can be used to identify extra or missing chromosomal material.

Figure 70-3 The formation of mosaicism. The X and Y chromosomes are used to illustrate two common errors leading to chromosomally abnormal cell populations. In normal mitosis (*top*), duplicated chromosomes separate and become incorporated into daughter cells. If one replicated chromosome fails to separate, mitotic nondisjunction occurs (*middle*). Occasionally, normal separation occurs, but one member fails to migrate. This is known as anaphase lag (*bottom*). (From Wisniewski LP, Hirschhorn K: *A Guide to Human Chromosome Defects*, 2nd ed. White Plains, NY, March of Dimes Birth Defects Foundation, Birth Defects:Original Article Series, vol 16, sec 6, 1980, with permission from the copyright holder.)

CHROMOSOMAL ABNORMALITIES

Chromosomal anomalies occur in 0.4% of live births. They are an important cause of mental retardation and congenital anomalies. Chromosomal anomalies are present in much higher frequencies among spontaneous abortions and stillbirths. The phenotypic anomalies that result from chromosomal aberrations are mainly due to imbalance of genetic information. Chromosomal anomalies include abnormalities of chromosome number and structure.

Abnormalities of Chromosome Number

Aneuploidy and Polyploidy.

When a human cell has 23 chromosomes, it is referred to as a *haploid cell* (the number of chromosomes in an ova or sperm). Any number of chromosomes that is an exact multiple of the haploid number (e.g., 46, 69, 92 in humans) is referred to as *euploid*. Euploid cells with more than the normal diploid number of 46 chromosomes are called *polyploid cells*. Polyploid conceptions are usually not viable. However, they may be present in mosaic (more than one cell line) forms, which allow survival. Cells with three sets of chromosomes are called triploid and are frequently seen in abortus material and occasionally in viable humans, usually in mosaic form. Cells deviating from the multiples of the haploid number are called *aneuploid* (i.e., not euploid), indicating a missing or extra chromosome.

Trisomies.

The most common abnormalities of chromosome number (aneuploidy) are trisomies. These occur when there are three representatives of a particular chromosome instead of the usual two. Trisomies are usually the result of meiotic nondisjunction (failure of a chromosome pair to separate). Trisomy may be present in all cells or may occur in mosaic form. Most individuals with trisomies exhibit a consistent and specific phenotype depending on the chromosome involved (Table 70–1). The most frequent trisomy in humans is *trisomy 21* or Down syndrome (Fig. 70–4). *Trisomies of chromosome 18* (Fig. 70–5) and *chromosome 13* (Fig. 70–6) are also relatively common and are associated with a characteristic set of congenital anomalies and mental retardation.

The incidence of Down syndrome among conceptions is more than twice as high as it is among live births. More than half the trisomy 21 conceptions spontaneously

abort early in pregnancy. The occurrence of trisomy 21 as well as other autosomal trisomies increases with advancing maternal age. The increased risk of trisomy 21 in women older than 35 yr is an indication to offer these women prenatal diagnosis. Amniocentesis, or chorionic villus sampling to examine the fetal chromosomes, is usually offered although maternal serum alpha fetoprotein screening and

TABLE 70-1 -- **Chromosomal Trisomies and Their Clinical Findings**

Syndrome	Incidence	Clinical Manifestations
Trisomy 13, Patau syndrome	1/10,000 births	Cleft lip often midline; flexed fingers with polydactyly; ocular hypotelorism, bulbous nose; low-set malformed ears; small abnormal skull; cerebral malformation, especially holoprosencephaly; microphthalmia; cardiac malformations; scalp defects; hypoplastic or absent ribs; visceral and genital anomalies
Trisomy 18, Edwards syndrome	1/6,000 births	Low birthweight, closed fists with index finger overlapping the 3rd digit and the 5th digit overlapping the 4th, narrow hips with limited abduction, short sternum, rocker-bottom feet, microcephaly, prominent occiput, micrognathia, cardiac and renal malformations, and mental retardation; 95% of cases are lethal in the 1st yr
Trisomy 21, Down syndrome	1/600–800 births	Hypotonia, flat face, upward and slanted palpebral fissures and epicanthic folds, speckled irises (Brushfield spots); varying degrees of mental and growth retardation; dysplasia of the pelvis, cardiac malformations, and simian crease; short, broad hands, hypoplasia of middle phalanx of 5th finger, intestinal atresia, and high arched palate; 5% of patients with Down syndrome are the result of a translocation—t(14q21q), t(15q21q), and t(13q21q)—in which the phenotype is the same as trisomy 21 Down syndrome
Trisomy 8, mosaicism	1/20,000 births	Long face, high prominent forehead, wide upturned nose, thick everted lower lip, microretrognathia, low-set ears, high arched, sometimes cleft palate. Osteoarticular anomalies are common; moderate mental retardation.

Figure 70-4 Partial karyotypes from patients with Down syndrome. *A*, Patient with trisomy 21. *B*, Chromosome 21 from two patients and their parents. *Left:* Two of a patient's chromosomes with brightly fluorescent satellites were transmitted by the mother. *Right:* Another patient's two chromosomes with bright satellites resulted from paternal nondisjunction at second meiotic division. *C*, 21q21q translocation. D, 14q21q translocation in a mother (*above*) and her affected child (*below*).

Note prominent occiput, micrognathia, low-set ears, short sternum, narrow pelvis, prominent calcaneus, and flexion abnormalities of the fingers. (Courtesy of Robert E. Carrel.) *B*, Several of the common anomalies in the 18 trisomy syndrome, including the unusual position of the fingers with hypoplasia of fifth fingernail, the simple arch pattern of the finger pads, and the dorsiflexed hallux with hypoplasia of toenails. (From Smith DW: Autosomal abnormalities. *Am J Obstet Gynecol* 1964;90:1055.) *C*, Partial karyotype of trisomy 18 prepared with modified Giemsa stain.

Figure 70-6 *A* and *B*, Female infants with trisomy 13 syndrome. Note the midline cleft of the lip and palate, microcephaly, hypotelorism, microphthalmos, bulbous nose, polydactyly, and overlapping of fingers. Scalp defects (not shown) are also present. (Courtesy of Miriam G. Wilson.) *C*, Partial karyotype showing chromosomes 13, 14, and 15 stained with the trypsin-Giemsa method.

recovering fetal DNA or cells from maternal blood are increasingly being used. In women younger than 35 yr of age, maternal serum testing (triple screen) can be efficacious in prenatal screening for Down syndrome. Low maternal serum a-fetoprotein concentration, low unconjugated estriol, and elevated human chorionic gonadotropin are indicators of Down syndrome. Prenatal ultrasonography may detect a thickened nuchal fold, absent nasal bone, a shortened femur, and cardiac or gastrointestinal anomalies associated with trisomy 21 (Chapter 85).

Translocation Down Syndrome.

All individuals with Down syndrome have three copies of chromosome 21. About 95% have three freestanding copies of chromosome 21. Approximately 1% of individuals are mosaic with some normal cells. Approximately 4% of Down syndrome individuals have a translocation involving chromosome 21. Translocations account for 9% of the children with Down syndrome born to mothers younger than 30 yr of age. Half the translocations arise de novo in the affected individual, whereas half are inherited from a translocation carrier parent. Parents who are carriers of a translocation involving chromosome 21 produce three types of viable offspring: normal phenotype and karyotype, a phenotypically normal translocation carrier, and the translocation trisomy 21. The majority of translocations that give rise to Down syndrome are fusions at the centromere between chromosomes 13, 14, 15, or 21, for example, t(13q,15q) or t(21q,21q). The phenotype in translocation Down syndrome is not distinguishable from regular trisomy 21 Down syndrome (see Table 70–1). Chromosome studies must be performed on every Down syndrome individual. If a translocation is identified, parental studies must be performed to identify normal individuals who are translocation carriers with a high recurrence risk for a chromosomally abnormal child and who may also have other family members at risk.

Monosomies.

Monosomies occur when only one representative of a chromosome is present. They may be complete or partial. Complete monosomies may be the result of nondisjunction or anaphase lag. In nondisjunction during cell division, the two chromosomes in a replicating pair fail to separate; one cell ends up with only one copy (monosomic) and the other with three copies (trisomic) of the specific

chromosome. In anaphase lag, a chromosome fails to move into the new daughter cell and is lost. In humans, all complete autosomal monosomies appear to be lethal early in development and only survive in mosaic forms. Partial monosomies are usually the offspring of a translocation carrier.

Abnormalities of Chromosome Structure

Deletions.

Deletions occur when a piece of a chromosome is missing. They may occur as a simple deletion or as a deletion with duplication of another chromosome segment. The latter is usually caused by a crossover in meiosis in a translocation carrier, resulting in an unbalanced reciprocal chromosomal translocation. Deletions may be located at the chromosome ends or in interstitial segments of the chromosome and are usually associated with mental retardation and malformations. Small telomeric deletions may be relatively common in nonspecific mental retardation with minor anomalies. The most commonly observed deletions in humans are 4p-, 5p-, 9p-, 11p-, 13q-, 18p-, and 18q-, which are associated with well-described phenotypes (Table 70–2). Deletions may be observed in routine chromosome preparations, but microdeletions are detectable only under the microscope with prophase chromosome studies. In submicroscopic deletions, the missing piece can be detected only by using molecular probes or DNA studies.

Microdeletions are defined as small chromosome deletions that are detectable only in high-quality (pro)metaphase preparations. These deletions often involve several genes so that the affected individual may be identified by an unusual phenotype associated with an apparent single gene mutation. Williams, Langer-Giedion,

TABLE 70-2 -- **Common Deletions and Their Clinical Manifestations**

Deletion	Clinical Abnormalities
4p-	Wolf-Hirschhorn syndrome. The main features are a typical “Greek helmet” facies with ocular hypertelorism, prominent glabella, and frontal bossing; microcephaly, dolichocephaly, hypoplasia of the eye socket, ptosis, strabismus, nystagmus, bilateral epicanthic folds, cleft lip and palate, beaked nose with prominent bridge, hypospadias, cardiac malformations, and mental retardation.
5p-	Cri-du-chat syndrome. The main features are hypotonia, short stature, characteristic cry, microcephaly with protruding metopic suture, moonlike face, hypertelorism, bilateral epicanthic folds, high arched palate, wide and flat nasal bridge, and mental retardation.
9p-	The main features are craniofacial dysmorphology with trigonocephaly, slanted palpebral fissures, discrete exophthalmos, arched eyebrows, flat and wide nasal bridge, short neck with pterygium colli, genital anomalies, long fingers and toes, cardiac malformations, and mental retardation.
13q-	The main features are low birthweight, failure to thrive, and severe mental retardation. Facial features include microcephaly, flat wide nasal bridge, hypertelorism, ptosis, micrognathia. Ocular malformations are common. The hands have hypoplastic or absent thumbs and syndactyly.
18p-	A few patients (15%) are severely affected and have cephalic and ocular malformations, cleft lip and palate, and varying degrees of mental retardation. Most (80%) have only minor malformations and mild mental retardation.
18q-	The main features are hypotonia with “froglike” position with the legs flexed, externally rotated, and in hyperabduction. The face is characteristic with depressed midface and apparent protrusion of the mandible, deep-set eyes, short upper lip, everted lower lip (“carplike” mouth); antihelix of the ears is very prominent; varying degrees of mental retardation and belligerent personality.
21q-	The main features are hypertonia, microcephaly, downward-slanting palpebral fissures, high palate, prominent nasal bridge, large low-set ears, micrognathia, and varying degrees of mental retardation. They may have skeletal malformations.

Prader-Willi, Angelman, Rubinstein-Taybi, Smith-Magenis, Miller- Dieker, Alagille, and velocardiofacial/DiGeorge syndromes have all been found to be associated with microdeletions (Table 70–3). Submicroscopic deletions are not visible by microscopic examination and are detected only with specific probes for a DNA sequence or DNA studies. The deletion is recognized because of the absence of staining or fluorescence.

Translocations.

Translocations involve the transfer of chromosomal material from one chromosome to another. Translocations may be Robertsonian or reciprocal. They occur with a frequency of 1/500 liveborn human infants. They may be inherited from a parent or appear de novo, with no other affected family members.

Robertsonian translocations involve two acrocentric (centromere located at the end) chromosomes that fuse near the centromeric region with subsequent loss of the nonfunctional, very truncated short arms. The translocation chromosome is made up of the long arms of two fused chromosomes, hence the resulting count is only 45 chromosomes. The loss of the short arms of acrocentric chromosomes has no known deleterious effect. Although carriers of a Robertsonian translocation are usually phenotypically normal, they are at increased risk for miscarriages and abnormal offspring. *Reciprocal translocations* are the result of breaks in nonhomologous chromosomes with reciprocal exchange of the broken segments. Carriers of a reciprocal translocation are usually phenotypically normal but also have an increased risk of having chromosomally abnormal offspring and miscarriages because of abnormalities in the segregation of the chromosomes in the germ cells.

Inversions.

Inversions require the chromosome to break at two points. The broken piece is then inverted and joined into the same chromosome. Inversions have a frequency of

1/100 liveborns and may be pericentric or paracentric. In *pericentric inversions*, the breaks are in the two opposite arms of the chromosome so that the intervening portion that contains the centromere is reversed. They are usually discovered because they change the position of the centromere. In contrast, *paracentric inversions* involve only chromosomal material from one arm of a chromosome. Carriers of inversions are usually normal, but they may have an increased risk of miscarriages and chromosomally abnormal offspring.

Ring Chromosomes.

Ring chromosomes are rare, but they have been found for all human chromosomes. The formation of a ring involves a deletion at each end of the chromosome. The "sticky" ends then join to form the ring. The phenotype of a ring chromosome ranges from mental retardation and multiple congenital anomalies to normal or nearly normal depending on the amount of chromosomal material that is lost. If the ring replaces a normal chromosome, the result is partial monosomy. The phenotype in these cases often overlaps that seen in comparable deletion syndromes of the same chromosome. If there is a ring in addition to the normal chromosomes, the phenotype reflects the partial trisomy for that chromosome.

Duplications.

A duplication is the presence of extra genetic material from the same chromosome. Duplications may result from the abnormal segregation in carriers of translocations or inversions.

Insertions.

Insertions occur when a piece of chromosome breaks at two points and is incorporated into a break in another part of a chromosome. This requires three breakpoints and may occur between two chromosomes or within one.

Telomere/Subtelomere Deletions.

Because chromosomes "cross over" during meiosis, small deletions and duplications of the regions toward the ends of the chromosomes occur relatively frequently. Subtelomeric rearrangements are being found increasingly (5–10%) in children with unexplained moderate to severe mental retardation without very obvious dysmorphic features. Submicroscopic subtelomeric deletions (smaller than 2–3?mb) are the second most common cause of mental retardation after trisomy 21. Clinical features seen in some of these children include prenatal growth retardation (seen in ~40%) and a family history of mental retardation (in 50%). Additional features seen in at least 30% of affected patients include microcephaly, hypertelorism, anomalies of the nose, ear, or hand, cryptorchidism, and short stature. FISH using multiple telomeric probes on metaphase chromosomes should be considered when other causes of developmental delay are excluded.

Sex Chromosome Anomalies

Turner Syndrome.

This is one of the most common monosomies in liveborn humans (see Chapter 580.1). The chromosomal finding in Turner syndrome is the loss of part or all of one of the sex chromosomes. Half the affected individuals have 45, X in their lymphocytes. The other half have a variety of abnormalities of one of their sex chromosomes and may be mosaic. The phenotype in Turner syndrome is female and is characterized by short stature and underdeveloped gonads. The frequency at birth is 0.4/1,000 (i.e., 1/4,000 liveborn females or 1/8,000 livebirths), but it occurs much more frequently in spontaneous abortions.

From 5–10% of individuals with Turner syndrome have some Y chromosome material in all or some cells. These individuals may have some masculinization and are at risk for the development of gonadoblastoma. A careful screening for Y chromosome material should be performed on any individual with Turner syndrome in whom no additional X chromosome (in addition to the one normal X) material has been found.

TABLE 70-3 -- **Microdeletions and Their Clinical Manifestations**

Deletion	Syndrome	Clinical Manifestations
7q11.23	Williams	Round face with full cheeks and lips, stellate pattern in iris, strabismus, supravalvular aortic stenosis and other cardiac malformations, varying degrees of mental retardation, and a very friendly personality
8q24.1-	Langer-Giedion or tricho-rhino- phalangeal, type II	Sparse hair, multiple cone-shaped epiphyses, multiple cartilaginous exostoses, bulbous nasal tip, thickened alar cartilage, upturned nares, prominent philtrum, large protruding ears, and mild mental retardation
11p13-	WAGR	Hypernephroma (Wilms tumor), aniridia, male genital hypoplasia of varying degrees, gonadoblastoma, long face, upward slanting palpebral fissures, ptosis, beaked nose, low-set poorly formed auricles, and mental retardation
15q11-13 (pat)	Prader-Willi	Severe hypotonia at birth, obesity, short stature (responsive to growth hormone), small hands and feet, hypogonadism, and mental retardation

15q11-13 (mat)	Angelman	Hypotonia, fair hair, midface hypoplasia, prognathism, seizures, jerky ataxic movements, uncontrollable bouts of laughter, and severe mental retardation
16p13-	Rubinstein-Taybi	Microcephaly, ptosis, beaked nose with low-lying philtrum, broad thumbs and large toes, and mental retardation
17p11.2	Smith-Magenis	Brachycephaly, midfacial hypoplasia, prognathism, myopia, cleft palate, short stature, behavioral problems, and mental retardation
17p13.3-	Miller-Dieker	Microcephaly, lissencephaly, pachygyria, narrow forehead, hypoplastic male external genitals, growth retardation, seizures, and profound mental retardation
20p12-	Alagille syndrome	Bile duct paucity with cholestasis, heart defects, particularly pulmonary artery stenosis, ocular abnormalities (posterior embryotoxin), skeletal defects such as butterfly vertebrae, long nose with broad midnose
22q11.2	Velocardiofacial-DiGeorge syndrome	Hypoplasia or agenesis of the thymus and parathyroid glands, hypoplasia of auricle and external auditory canal, conotruncal cardiac anomalies, cleft palate, short stature, behavioral problems

Klinefelter Syndrome.

These individuals have a male karyotype with an extra X chromosome, 47, XXY, and the phenotype is male (see Chapter 577.1). Individuals with Klinefelter syndrome are usually relatively tall. They may have gynecomastia, and secondary sex development may be delayed. They usually have azoospermia and small testes, and are infertile.

Many other syndromes occur in which there are extra X chromosomes (i.e., 47, XYX, 48, XXY-X, 49, XXXXX, 48, XXXY, and 49, XXXXY). These individuals are often mosaic, having both normal and abnormal cell lines (46, XX/47, YXX). In all these syndromes, the number of abnormalities increases with the number of X chromosomes and is specific to each syndrome. Abnormalities of chromosome Y also exist. The most common abnormality is the XYY male.

47, XYY Male.

The frequency of XYY males has been estimated to be 1/1,000 livebirths. Because XYY males do not have any striking phenotypical abnormality, this frequency has been estimated from newborn surveys. XYY males are said to be relatively tall and may have some behavioral problems.

Fragile Sites

Fragile sites are defined as regions of chromosomes that show a tendency to separation, breakage, or attenuation under particular growth conditions. Numerous fragile sites have been identified.

Fragile X Syndrome.

The fragile site located on the distal long arm of chromosome X at Xq27.3 is associated with the Fragile X syndrome, which is the most common heritable form of mental retardation in males. This fragile site (FRAXA) becomes visible in chromosome studies only when it is induced under special culture techniques; regular metaphase studies do not demonstrate this fragile site. The fragile site may not always be visible, even with the appropriate chromosome preparation. The diagnosis of fragile X is made by DNA studies, which demonstrate an expanded segment of DNA from the Xq27.3 region. The length of the expanded segment reflects the number of nucleotide triplet repeats. There are two other fragile sites on the X chromosome (FRAXE and FRAXF) also associated with mental retardation and allelic expansion.

The main *clinical manifestations* of Fragile X syndrome in affected males are mental retardation; macroorchidism; large size; characteristic facial features, including long face, prominent jaw, and large prominent ears; stereotyped behavior and speech. Females affected with Fragile X show varying degrees of mental retardation; however, it is a less frequent cause of mental retardation in girls.

The *inheritance of Fragile X* is different from the usual single-gene inheritance patterns. It involves an area of the gene with CGG/CCG repeats (triplet repeats). Three distinct categories of DNA variation occur at the fragile X locus (normal, up to 50 repeats; premutation, 52–200 repeats; symptomatic, 200–2,000 repeats or greater). A person who carries a small increase of trinucleotide repeats without the phenotypic abnormalities is said to be a carrier of a premutation. When inherited, this premutation is unstable and may expand over a few generations, gradually increasing in size when transmitted by females but usually remaining the same size when transmitted by males. When the mutation is transmitted by a female and increases in size, it may become a size (usually an additional 600–3,000 base pairs) that is clinically significant and leads to the typical Fragile X syndrome phenotype with mental retardation. Also see Chapter 68 .

Allelic expansion refers to the change of the size of the DNA sequence. Allelic expansion interferes with gene function. The expansion begins as a small increase in the copy number of trinucleotide repeats. The number of repeats is unstable and may lead to different sizes in different cells or tissues. The number of repeats may increase in size from one generation to the next (but occasionally may decrease in size). A change in size of the DNA segment between generations or in tissues means that this type of mutation differs from classic mutations in which the change in DNA sequence usually occurs once and is then passed on from generation to generation. Other disorders associated with allelic expansion include myotonic

dystrophy (with CTG repeats), Huntington disease (with CAG repeats), spinobulbar muscular atrophy (with CAG repeats), spinocerebellar ataxia type 1, 2, and 3 (SCA1, SCA2, and SCA3, all with CAG repeats), and dentatorubral-pallidoluysian atrophy (with CAG repeats).

The number of copies seen in disorders associated with allelic expansion seems to determine the age of onset and severity of the disease (Table 70–4). For example, the congenital form of myotonic dystrophy is known to occur with the largest number of repeats but only when the mother transmits it. In Huntington disease, the juvenile onset form of the disease is also associated with the largest number of repeats and occurs primarily when inherited from the father.

Chromosomal Breakage Syndromes

There are a number of recessive disorders that are associated with breakage or rearrangement of chromosomes, or both. The breaks may be spontaneous or they can be induced by a variety of environmental agents and brought out by different laboratory techniques. Chromatid breaks are found in Fanconi anemia, Nijmegen syndrome, Bloom syndrome, and Werner syndrome. Breaks and

TABLE 70-4 -- **Allelic Expansion**

Gene	Location	Normal	Premutation	Affected	Parent of Origin Effect
Huntington disease	4p16.3	11–24 repeats	30–38	42–82	Male transmission usually increases repeat
Myotonic dystrophy	19q13.3	5–37 repeats	37–50	>50	Male may decrease repeat Female usually increases repeat
Fragile X	Xq23.7	6–54 repeats	52–200	>200	Male constant Female may markedly increase repeat

nonrandom rearrangements of chromosomes 7 and 14 have been reported in ataxia-telangiectasia. A special cytogenetic study, sister chromatid exchange, is used in some of these disorders for carrier detection and prenatal diagnosis. These disorders have specific phenotypes, but the growth impairment, malformations, and other dysmorphic features seen in these conditions have not been directly attributed to the chromosome breaks.

Mosaicism

Mosaicism is the term used to describe an individual who has two different cell lines derived from a single zygote (fertilized egg) (see Fig. 70–3). Studies of placental tissue from chorionic villus sampling show that at least 2% of all conceptions are mosaic for chromosomal anomalies at or before 10 wk of pregnancy. Compared with complete trisomies, which are usually nonviable for chromosomes other than 13, 18, and 21, the development of a normal cell line may allow a trisomic conception of the other chromosomes to continue to term and be viable. If a normal cell line develops, the fetus may survive and the original trisomic cell line may even be lost. Normal disomic cells are found in the placenta of infants who are born alive with trisomies 13 and 18.

Germ line mosaicism refers to the presence of mosaicism in the germ cells found in the gonad. This type of mosaicism may be suspected in cases in which there is more than one affected offspring with the same genetic abnormality (usually inherited as a chromosomal or autosomal dominant disorder) with phenotypically normal parents. If germ line mosaicism is present, there is an increased risk for recurrence of an affected child.

Depending on the point at which the new cell line arises during early embryogenesis, an affected individual may have a variety of clinical presentations. Mosaicism may be present in some tissues and not in others, giving the affected individual a patchy or asymmetric distribution of abnormalities. Cytogenetic studies of fibroblasts must be performed if mosaicism is suspected because blood lymphocyte cells may not tolerate some trisomies, deletions, or chromosomal rearrangements, and thus the finding of normal lymphocyte studies will be misleading.

Pallister-Killian Syndrome.

This disorder is characterized by coarse facies, pigmentary skin anomalies, localized alopecia, diaphragmatic hernias, cardiovascular anomalies, supernumerary nipples, and profound mental retardation. The syndrome is due to mosaicism for isochromosome 12p. The presence of the isochromosome 12p in cells gives four copies of 12p in the affected cells. The isochromosome 12p is preferentially cultured from fibroblast and is seldom present in lymphocytes. The abnormalities seen in affected individuals probably reflect the presence of abnormal cells during early embryogenesis.

Hypomelanosis of Ito.

This entity is characterized by unilateral or bilateral macular hypopigmented whorls, streaks, and patches. Abnormalities of the eyes, musculoskeletal system, and central nervous system may also be present. Patients with hypomelanosis of Ito appear to have two genetically distinct cell lines. The mosaic chromosome anomalies that have been observed involve both autosomes and sex chromosomes and have been demonstrated in about 50% of cases. The mosaicism may not be visible in chromosome studies carried out on blood but is more likely to be found when the chromosome studies are obtained from skin fibroblasts. Sometimes the distinct cell lines may not be due to observable chromosomal anomalies but to single gene mutations or other mechanisms.

Acquired Cytogenetic Abnormalities

Chromosomal changes are seen in most cancers. It is thought that the chromosomal change affects cancer-promoting and cancer suppressing genes. Loss, gain, and translocations of chromosomes are seen in cancerous tissue, which appear to alter the function of cancer related genes. The particular rearrangements may be useful in predicting prognosis and suggesting the most efficacious therapy.

UNIPARENTAL DISOMY

Uniparental disomy (UPD) is the term used when both chromosomes of a pair of chromosomes in a person with a normal number of chromosomes have been inherited from only one parent. Uniparental isodisomy means that the two chromosomes are identical, whereas uniparental heterodisomy means that the two chromosomes are different members of a pair, both of which were inherited from one parent. The phenotypical result of UPD may vary according to the specific chromosome involved, the parent who contributed the chromosomes, and whether it is isodisomy or heterodisomy. Three types of phenotypic effects are seen in UPD: (1) those related to imprinted genes (see later), that is, the absence of a gene that is expressed only when inherited from a parent of a specific gender, (2) those related to autosomal recessive disorders, and (3) those related to a vestigial aneuploid producing mosaicism. Also see Chapter 69 .

In uniparental isodisomy, both chromosomes in the pair are identical; consequently, the genes on both chromosomes are also identical. This becomes particularly important when the parent is a carrier of an autosomal recessive disorder. If the offspring of a carrier parent has uniparental disomy with isodisomy for a chromosome that carries an abnormal gene, the abnormal gene will be present in two copies and the phenotype will be that of the autosomal recessive disorder. In other words, the child has an autosomal recessive disorder when only one parent is actually a carrier of that recessive disorder. It is estimated that all human beings carry five to eight abnormal autosomal recessive genes. The autosomal recessive disorders spinal muscular atrophy, cystic fibrosis, cartilage-hair hypoplasia, a- and ß-thalassemias, and Bloom syndrome have occurred because of uniparental disomy. The possibility of uniparental isodisomy should also be kept in mind when an individual is affected with more than one recessive disorder because the abnormal genes for both disorders could be carried on the same isodisomic chromosome. Uniparental isodisomy is a very rare cause of recessively inherited disorders.

Maternal uniparental disomy involving chromosomes 2, 7, 14, and 15 and paternal uniparental disomy involving chromosomes 6, 11, 15, and 20 are associated with phenotypic

Figure 70-7 In pedigrees suggestive of paternal imprinting, phenotypic effects occur only when the gene is transmitted from the mother but not when transmitted from the father. There are equal numbers of males and females affected and nonaffected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; in other words, in paternal imprinting there are “skipped” female nonmanifesting individuals.

abnormalities of growth and behavior. For instance, UPD maternal 7 is associated with a phenotype similar to Russell-Silver syndrome with intrauterine growth retardation. These phenotypic effects may be related to imprinting (see later).

UPD for chromosome 15 is seen in some cases of Prader-Willi syndrome and Angelman syndrome. In *Prader-Willi syndrome*, about 60% of cases have maternal UPD (i.e., missing the paternal chromosome 15). In about 5% of individuals with *Angelman syndrome*, paternal UPD of chromosome 15 is observed (i.e., missing the maternal chromosome 15). The phenotype for both Prader-Willi syndrome and Angelman syndrome in cases of UPD is thought to be due to the lack of the functional contribution from a particular parent of their chromosome 15. These findings suggest there are differences in function of certain regions of chromosome 15, depending on whether it is inherited from the mother or from the father.

Uniparental disomy most likely arises because a pregnancy starts off as a trisomy. Most trisomies are lethal, and the fetus survives only if a cell line loses one of the extra chromosomes and becomes disomic. One third of the time, the disomic cell line is uniparental. Usually, the viable cell line outgrows the trisomic cell line. When mosaic trisomy is found at prenatal diagnosis, care should be taken to determine whether uniparental disomy has resulted and whether the chromosome involved is one of the disomies known to be associated with phenotypic abnormalities. There must always be concern that some residual cells that are trisomic will be present in some tissues, leading to malformations or dysfunction. The presence of aggregates of trisomic cells may account for the spectrum of abnormalities seen in individuals with UPD.

IMPRINTING

Genomic imprinting refers to the observation that phenotypic expression depends on the parent of origin for certain genes and chromosome segments. Whether the genetic material is expressed depends on the gender of the parent from whom it was derived. Genomic imprinting is suspected on the basis of a pedigree (Figs. 70–7 and 70–8) with unusual transmission. Imprinting probably occurs in many different parts of the human genome but is thought to be particularly important in gene expression related to development, growth, cancer, evolution, and behavior.

Imprinting in humans is noted by phenotypic differences seen in Prader-Willi and Angelman syndromes, which are associated with deletion and uniparental disomy of the same region of chromosome 15. Thus in uniparental maternal disomy, there is also lack of the paternal segment of chromosome 15, resulting in Prader-Willi syndrome as well. In Prader-Willi syndrome, the deletion, when it occurs, is always of the paternally derived chromosome 15, suggesting that the phenotype of Prader-Willi is due to a lack of paternally derived genetic information carried on that segment of chromosome 15. In contrast, when there is a deleted chromosome 15 in Angelman syndrome, the deleted chromosome is always maternal in origin, and the UPI is always paternal, that is, there is lack of maternal information. There are

Figure 70-8 In pedigrees suggestive of maternal imprinting, phenotypic effects occur only when the gene is transmitted from the father but not when transmitted from the mother. There are equal

numbers of males and females affected and nonaffected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; in other words, in maternal imprinting there are "skipped" male nonmanifesting individuals.

likely to be many other disorders with this type of parent of origin effect.

Chapter 71 - Gene Therapy

Mark A. Kay

Gene therapy is defined as the introduction of nucleic acids into a tissue to prevent, inhibit, or reverse a pathologic process. Gene therapy was initially considered to treat monogenic disorders; DNA should also be considered to treat both genetic and acquired disorders. Gene therapy is usually restricted for somatic cell therapy. Genetic modification of human germ cells is not currently acceptable. Most of the current clinical trials are performed on adults who are able to give informed consent for experimental procedures. Exceptions may include life-threatening diseases in children for whom no alternative therapy is available. However, as safety and success become demonstrable, gene therapy is likely to impact disease prevention. Currently, there is only one accepted and unequivocal therapeutic benefit in treated patients with X-linked severe combined immunodeficiency (SCID).

GENE TRANSFER STRATEGIES

Most gene therapy involves transferring DNA into target tissues to add expression of the exogenous gene that encodes a protein missing due to a gene mutation or to supply a novel protein with a desired pharmacologic effect. In this situation, the exogenous gene, referred to as the *transgene*, is not localized in the normal chromosomal location in the human genome. Nonetheless, by adding the appropriate promoters or regulatory elements, the added gene can be expressed in the targeted cells (Fig. 71–1). Generic problems include achieving therapeutic levels of gene transfer into the appropriate cell types, control of gene expression, immune reactions to the vector or gene product and the risk of insertional mutagenesis. In some acquired disorders (e.g., cancer or acute infection), short-term transgene expression is desirable; for most genetic diseases, lifelong genetic modification is required.

A second type of gene therapy involves the insertion of nucleic acid in a formulation that instead of randomly inserting itself into a cell's DNA will actually correct a mutation in chromosomal DNA, reverting the inactive gene into a functioning gene or converting an abnormally functioning gene back to normal. Even though there are attractive advantages to correcting a mutation rather than adding exogenous DNA that can in theory have unwanted side effects, it will be very difficult to use gene correction technology to treat diseases where there are hundreds of mutations that cause the same phenotypic disease. This therapy is limited to the treatment of monogenic disorders.

With the clinical efficacy of enzyme replacement for disorders such as Gaucher disease, it may not be obvious why there is an advantage to producing a therapeutic protein within the body compared with exogenous protein therapy. In some cases, it is not possible to target exogenous proteins to the correct tissue or intracellular location required for function. Production of a therapeutic protein within a tissue may achieve a much higher local concentration and may avoid systemic toxicity derived from parenteral protein administration. It is difficult to achieve a constant therapeutic level of most proteins when administered exogenously. Gene transfer produces constitutive and thus steady-state levels of the desired protein.

Gene therapy can be performed ex vivo or in vivo. In ex vivo gene therapy, the target cells are removed, genetically manipulated in the laboratory, and then readministered to the patient. This is not unlike gene therapy with an organ transplant (liver for hyperlipidemia) or a cell transplant (bone marrow for lysosomal diseases) except that it uses autologous cells that are less likely to be immunogenic and lost due to rejection. Even though this approach is easily adaptable to some cell types, including bone marrow derived cells or fibroblasts, it is less feasible to perform in most other tissues. The goal of in vivo gene therapy is to deliver the vector and gene by intravenous infusion or oral or respiratory administration. The vector would then home to the appropriate target organs with minimal dissemination to unnecessary tissues. Further safeguards include using regulatory sequences attached to the gene that only allows for transgene transcription in the targeted tissue.

An important consideration is the risk of humoral immune responses against the corresponding transgene product and/or cellular immune responses directed against the gene-modified cells. This is especially problematic in individuals with genetic disorders who have never been exposed to the normal protein (gene deletions). Polymorphic genetic variances in humans make it likely that responses to gene therapy trials will be much more variable in humans than in inbred animals. Preclinical testing in animals is required before proceeding into human trials, but the limits of animal testing must be considered.

VECTORS–THE VEHICLES OF GENE TRANSFER

Gene transfer vectors are either viral or nonviral (Table 71–1). Viruses are efficient vehicles for transferring genetic information into host cells. The viral shell serves as the physical carrier of the genetic sequences to be transferred into the target cell (see Fig. 71–1). The vector DNA cannot replicate in the absence of viral genes and make new viral particles. The genetic structure of many vectors contains only viral DNA at both ends, which do

Figure 71-1 Life cycle and organization of wild type and recombinant retrovirus genomes. Retroviruses bind to specific cellular receptors on the target cell surface and are internalized by receptor-mediated endocytosis. Following entry, the retroviral RNA genome is removed from its capsid coat and is reverse transcribed by viral reverse transcriptase into DNA that is transported to

the nucleus, where integration into the host genome occurs. In wild-type virus, the life cycle is completed by the synthesis of viral proteins and RNA by the host cell, packaging the retroviral particle that is released by budding from the cell surface. Recombinant viruses containing the therapeutic gene or cDNA are replication incompetent, the insert taking the place of the viral genes *GAG*, *POL*, and *ENV*. "Packaging" lines produce these retroviral gene products in vitro, allowing encapsulation of virus and production of the infectious virions. The "packaged" recombinant virus contains an RNA copy of the therapeutic gene insert that can be used to infect target cells.

not encode viral genes (see Fig. 71–1). The structural ends of the viral vector are recognition signals for packaging the vector DNA into encapsulated virion particles. When a virus is used as a vector, safety concerns related to the inadvertent production of contaminating wild-type (disease causing) virus is important. There is great effort in developing ways to deliver DNA molecules in the absence of viruses. These include naked DNA and complicated chemical formulations conjugated to the DNA (see Table 71–1). One important limitation is the ability to safely transfer the genes into a specific organ with therapeutic efficiency,

TABLE 71-1 -- **Properties of Transfection Agents**

Transfection Agent	Cell Target	Chromosomal Integration	Immunogenicity	DNA-Carrying Capacity in Kb
Naked DNA	Skeletal muscle, thyroid gland, certain tumor types, liver cells, skin, myocardial cells	No	No	>10
Retrovirus	Dividing cells	Yes	Low	9
Adenovirus	Dividing and nondividing cells	No, episome	High in first generation, Low in mice	38 8 27
Lentivirus	Dividing and nondividing cells	Yes	Low	<8
Adeno-associated virus	Many cells	Rare	Low	<5
Herpes simplex virus	Neurons of sensory ganglia	Extra-chromosomal	Low	25
Liposome	Many cells	Episome	Low	>10
Protein/peptide	Many cells	Episome	Variable	>10

From Balicki D, Beutler E: Gene therapy of human disease. Medicine *2002;81:69–86.*

resulting in persistent gene expression. In general, viral vectors appear to offer more immediate promise for efficacy, although many future vectors will likely be nonviral.

Retroviral based vectors are the most commonly used vector. The type of retroviral vector used clinically is based on a mouse Moloney retrovirus. These vectors are deleted of all of their viral genes and have a relatively long safety record. To produce the vector, packaging cell lines that are permanently modified with all of the viral genes required for replicating and packaging the vector genome are used (see Fig. 71–1). The vector sequences that contain the therapeutic gene is flanked by structural viral sequence and the packaging signal; a sequence required for packaging the vector DNA into the virion flanks the gene expression cassette. In this approach, only the vector sequences encoding the therapeutic gene of interest are packaged into the viral particle. When exposed to the target cells, the vector genome containing only the therapeutic gene, and no viral genes, is transduced into cells. Retroviral vectors integrate their therapeutic genes into the chromosomes of target cells. This results in stable gene transfer as long as the modified cell or their progenitors survive. This offers an advantage for genetic diseases in which lifelong gene expression is required. Even though these vectors have a long safety record in animal and human trials, the concern with any vector that has the potential to integrate is insertional mutagenesis causing inactivation or overactivation of an unrelated cellular gene that may be involved in carcinogenesis. This vector only transduces cells that are actively dividing. At any one time, most cells in a tissue are not dividing. Unless a stimulus is used to promote cell division, gene transfer efficiencies are low. Most retroviral-based gene transfer clinical protocols are based on ex vivo studies in which the patient's cultured cells (bone marrow) are manipulated in the laboratory to undergo cell cycling. Newer retroviral-based vectors derived from lentiviruses such as HIV have the possible advantage of transducing some cell types that are not actively dividing. Concerns with any viral vector are related to the overlap sequences with wild-type viruses that could result in recombination events leading to the creation of wild-type or rearranged virus. However, with current vector designs, overlap sequences have been eliminated or are very short, making recombination less of a concern.

Recombinant adenoviral vectors do not integrate and can transduce a large proportion of the cells in many different tissues (see Fig. 71–1). The genomic structure of the adenovirus is more complex than that of the retrovirus, and as a result it has been more difficult to remove all of the viral genes from the vectors. The remaining viral genes that are left in the early versions of the vector are transcribed at a very low level, resulting in some level of toxicity and immunogenicity. Whereas adenovirus may offer some advantage in treating diseases such as cancer, the associated vector toxicity resulted in the death of a young man after intravascular infusion. The preclinical studies suggest that vectors without any viral genes have much reduced toxicity.

Recombinant adeno-associated viral vectors are derived from a nonpathogenic human parvovirus. This vector has an outstanding safety record and is efficient at transducing a number of tissues, including the muscle and liver. Clinical trials are

ongoing for cystic fibrosis, hemophilia, and muscular dystrophy. The major disadvantage of this vector is that, as a result of its small size, it cannot carry very large genes, which limits its applications for some disorders.

Herpes viruses are probably the least well understood. They are large, have a large DNA capacity, and are efficient at transducing many tissues, including the central nervous system. Preclinical studies are underway and clinical trials are likely to be initiated soon.

Nonviral vectors are made by several different methods and usually consist of DNA complexed with lipids, carbohydrates, proteins, and/or other synthetic chemicals to facilitate delivery or increase vector stability. Gene delivery with naked DNA is also possible; however, the inefficiency of this process probably limits its use. Nonviral vectors are desirable because they eliminate the risk of viral contamination and can be produced under more controlled conditions. Their major disadvantage is low gene transfer rates, at least when compared with most viral vector systems. Novel methods involving coexpression of the vector with protein molecules allow for vector-specific integration into cultured cells or animals. Even though proof-of-concept studies have been demonstrated, additional safety studies are required before clinical implementation will be considered.

For viral vectors, most of these properties are based on the mechanism by which the parent virus is known to infect cells in the wild-type state. Because of these inherent properties, there is great interest in making hybrid vectors that contain desired properties of two different vectors combined into a single vector. Thus future viral vectors may be derived from more than one virus or represent a combination of viral and nonviral components.

Because many of the vectors under development are derived from viruses, similar to what occurs with infection, humoral immunity may prohibit secondary gene transfer with repeated vector administration. Readministration may require a vector derived from a different viral serotype.

TARGETING GENE DELIVERY

An important aspect of gene transfer is expression of the protein in the target or other functional cells. Biologically active factor IX is normally produced in liver, but it can be produced and secreted into the bloodstream via the muscle, endothelium, or fibroblasts. In contrast, globin production for hemoglobinopathies requires regulated gene expression in erythroid-derived cells. It may be possible to deliver the vector into a specific tissue (intramuscular injection for muscle delivery). Retargeting the vector by altering the viral ligand will only allow it to enter the desired cell type. Gene promoter regulatory elements can successfully turn genes on or off in a tissue-specific manner.

Viruses bind to cells based on their outer coat protein and availability of a viral receptor on the host cell. To alter tropism and to get tissue specific uptake of a viral vector, genetic modification of the viral outer proteins is required. Pseudotyping or swapping one coat protein with one derived from a different virus is possible. True tissue-specific engineering of the viral ligand has had technical difficulties. Finally, in some diseases, the ability to turn the gene on or off at desired times, such as with the insulin gene in diabetes (e.g., *on* during high glucose and *ofi* during low glucose), is required for successful treatment. Regulatory sequences that respond to blood sugar levels have been used. Moreover, drug responsive genes have been constructed such that the gene is either turned on or off with exposure to a specific drug.

DISEASE TARGETS

Even though gene therapy was originally considered for the treatment of monogenic disorders, of the more than 500 clinical trials to date, only about 10% of the proposed or ongoing trials are directed at treating genetic diseases (Table 71–2). Most of the clinical trials are designed to treat cancer. Four major approaches to treat cancer have been considered:

TABLE 71-2 -- **Candidate Diseases for Gene Therapy**

Single Gene Defects	Genes Involved	Target Organs/Tissues
Severe combined immunodeficiency	Several	T cells
a_1 -Antitrypsin deficiency	a_1 -Antitrypsin	Lungs (emphysema), liver (cirrhosis)
Cystic fibrosis	Cystic fibrosis transmembrane regulator	Lungs, pancreas
Hemophilia A and B	Factors VIII and IX	Blood clotting
Gaucher disease	Acid ß-glucosidase, glucocerebrosidase	Macrophages; liver, spleen, lungs
ß-Hemoglobinopathies	ß-Globin	Blood formed elements
Hypercholesterolemia, familial	LDL receptor	Liver; vascular, endothelial; smooth muscle cells
Phenylketonuria	Phenylalanine hydroxylase	Liver

Complex Traits	Genetic Approach	Target Organs/Tissues
Cancer	Cytokine, HLA genes, thymidine kinase, p53 lytic	Various
HIV-1	Antisense constructs, immunoenhancers	Immune system

HIV=human immunodeficiency virus; HLA=human leukocyte antigen; LDL=low-density lipoprotein.

1. *Immune response*. An immune response can result in a robust killing of tumors, thus gene transfer of genes that express potent tumor-specific antigens resulting in a more immunogenic tumor and/or genes for cytokines that stimulate and/or bring more immune-responsive cells to the tumor would be beneficial.

2. *Replacement of tumor suppressor genes*. Administration of genes known to be inactivated in tumors, and at least in part responsible for cellular transformation, can be added to the tumors to revert the cells to a nonmalignant phenotype. It is difficult to envision how this type of approach will be curative because it is unlikely that any vector can truly transduce 100% of malignant cells.
3. *Gene induced toxicity*. The transfer of toxic genes directly to the tumor or neighboring cells is another approach. Transfer of a gene into surrounding tissues that affect tumor vascularization may be effective. Direct targeting of tumor cells with toxic genes or genes that allow prodrug activation into a toxin have been considered. The best example is the thymidine kinase gene (derived from herpes simplex virus), which converts ganciclovir into a DNA analog that interrupts cellular DNA replication resulting in cell death.
4. *Replication lytic viruses*. Some lytic viruses have been engineered to selectively replicate in tumor cells, allowing them to propagate and kill the infected cells.

The demonstration of clinical efficacy as measured by survival has been hampered because most of the clinical trials have been performed in advanced stages of malignancy when all other medical interventions have failed. Gene transfer in the early stages of tumorigenesis greatly enhances the probability of ablation of the tumor. At some point, clinical trials will have to be performed in early onset disease when the therapy has the best chance of being clinically efficacious.

The first effective gene therapy trial was for X-linked SCID due to a deficiency in the interleukin-2 receptor gamma chain gene. These patients have essentially no antigen-specific immunity because of the loss of T cells. Bone marrow–derived cells, which contained a population of “stem” or self-renewing progenitor cells, were removed and transduced with a retroviral vector that expressed the missing protein. Genetically reconstituted cells have a selective advantage and can repopulate the missing T cells. Interestingly, this selective repopulation was sufficient to restore immune function in treated individuals. One patient developed a T cell leukemia like tumor. Insertional mutagenesis is a possible but unproven etiology. Similar positive results were noted when bone marrow or cord blood stem cells were transduced to treat SCID due to adenosine deaminase deficiency. Fanconi anemia is another disease in which a selective advantage has been postulated and a low level of gene transfer may be therapeutic. However, there are at least eight different genes that can cause this disease, requiring a different vector for each. Although bone marrow–derived gene transfer offers hope in treating many diseases, in disorders in which no selective advantage is conferred, higher efficiency gene transfer into stem cells will be required. The rate-limiting step for gene transfer into these cells has not been definitively established.

Gene therapy trials are ongoing for a number of other diseases (see Table 71–2). Gene therapy for cystic fibrosis is complicated by the uncertainty of which cell type is the most critical for gene replacement, the number of cells that need to be genetically modified for clinical efficacy, and the longevity of gene correction in target cells. There are a number of clinical end-points that are possible to measure but the most relevant for establishing success is unclear. Moreover, the lung has evolved efficient barriers to keep viruses out of respiratory epithelium, making it a tough barrier to penetrate. Even though all of the clinical trials have been related to gene addition strategies, because a single mutation (?F508) makes up 75% of the mutant alleles, gene correction strategies are viable alternatives.

Hemophilia has been an attractive disease for developing gene transfer strategies. Unlike for cystic fibrosis, the clinical end-points are clear; reconstitution of the plasma with at least 1% of the normal level of coagulation factor VIII or IX in hemophilia A and B, respectively, can convert an individual with severe disease to a much milder phenotype. Even though factor IX is exclusively and factor VIII is primarily made in the liver, not all of the gene therapy attempts for treatment involve the reconstitution of factor production in the liver. Many different approaches include intravenous and/or intramuscular infusions of recombinant retroviral, adenoviral, or adeno-associated viral vectors, ex vivo transplantation of genetically modified fibroblasts, implantation of biochambers containing genetically modified cells, and genetic modification of various endothelial or stem cells.

Vectors derived from adenovirus and adenovirus-associated virus (AAV) are efficient at transferring genes into cells within the central nervous system and skeletal muscle. There is a great interest in attempting to treat neuromuscular and neurodegenerative diseases. Generalized neurodegenerative disorders, especially those that are prenatal in onset are not likely to be treatable with gene therapy in the near future. In contrast, canine models of retinitis pigmentosa have recently been treated.

Expression of a foreign protein from a gene transfer vector can result in a robust humoral or cellular immune response, suggesting that gene transfer can be used in vaccine development. The concept is to express small amounts of the foreign antigen and/or cytokines from antigen presenting cells, resulting in a more robust immune response than for protein-based vaccines. Because transient as well as small amounts of protein synthesis are required in vaccine development, nonviral DNA plasmids have been used for this purpose in early clinical trials. The hope is that this therapy can be developed for current protein vaccines that are not very immunogenic.

Gene transfer approaches for treating acquired infections are being tested. The goal is to interfere with the viral life cycle at different stages of infection, replication, and/or viral assembly. Expression of antiviral proteins (e.g., cytokines, interferon) or

protein decoys that interfere with viral proteins critical for viral replication are two current strategies. Therapeutic nucleotides that do not encode proteins but interfere with the viral life cycle also show promise. Molecules known as ribozymes, DNAzymes and antisense and small interfering RNAs are short stretches of nucleotides, which can be delivered directly or expressed from gene transfer vectors. In laboratory studies, these approaches have been shown to either inhibit viral protein synthesis and/or enhance the degradation of the pathogenic viral genome.

Gene transfer strategies for the treatment of juvenile diabetes resulting from

autoimmune destruction of beta cells require additional approaches because the target cells are destroyed during the pathogenesis of the disorder. Strategies for therapy include introducing genes into the pancreas or liver progenitor cells that can differentiate into insulin-producing beta cells, or transfecting the insulin gene into hepatocytes containing a glucose-responsive element that regulates gene transcription.

Chapter 72 - Genetic Counseling

Judith G. Hall

When a child is born with multiple congenital anomalies or a family is diagnosed with a genetic disorder, talking with the family is not easy. Giving bad news is always difficult, and the information is often somewhat technical. However, it is important to provide the family with as much information as possible so that they can make informed decisions. Genetic counseling has been defined as an educational process that seeks to assist affected and/or at risk individuals to understand the nature of a genetic disorder, its transmission, and the options available to them in management and family planning. There are many indications for genetic counseling. (Box 72–1).

Although the task of providing information about genetic diseases is often done by a team of highly trained medical geneticists and genetic counselors, the information may also be provided by an experienced family physician, pediatrician, or nurse. Genetic counseling must be done based on an understanding

Box 72-1. Indications for Genetic Counseling

- Advanced parental age
    - Maternal age >35 yr
    - Paternal age >50 yr
- Child with congenital anomalies or dysmorphology
- Consanguinity or incest
- Family history of heritable disorders or diseases, including:
    - Adult onset
    - Complex/multifactorial inheritance
    - Chromosomal abnormality
    - Single gene disorders
- Heterozygote screening based on ethnicity, including:
    - Sickle cell anemia (West African, Mediterranean, Arab, Indo-Pakistani, Turkish, Southeast Asian)
    - Tay-Sachs, Canavan (Ashkenazi-Jewish, French-Canadian) Thalassemias (Mediterranean, Arab, Indo-Pakistani)
- Pregnancy screening abnormality, including:

    - Prenatal ultrasound examination
- Stillborn with congenital anomalies
- Teratogen exposure or risk

of genetic principles, the ability to recognize and diagnose genetic diseases and rare syndromes, and knowledge of the natural history of the disorder and its recurrence risk. Awareness of prenatal diagnosis and screening programs available in a particular region and access to information about advances in genetic disorders and medical techniques are also necessary.

With the sequencing of the human genome, most people think it should be possible to identify the genes responsible for an inherited disorder. However, only about 10% of known or described conditions have had the responsible gene identified. Furthermore, other genes and the environment modify most gene expression so that a wide spectrum of effect can be expected. Developments in molecular genetics provide many options for modification of gene expression, use of alternative pathways, and application of therapeutic approaches once the specific disorder and responsible genes are identified.

TALKING TO FAMILIES

The type of information provided to a family depends on the urgency of the situation, the need to make decisions, and the need to collect additional information. However, there are three general situations in which genetic counseling becomes particularly important.

The first is the prenatal diagnosis of a congenital anomaly or genetic disease. This is a very difficult situation, and the need for information is urgent because a family must often decide whether to continue or to terminate a pregnancy. Risks to the mother must also be considered. The second type of situation occurs when a child is born with a life-threatening congenital anomaly or genetic disease. This also requires urgent information and decisions that must be made immediately with regard to how much support should be provided for the child and whether certain types of therapy should be attempted. The third situation arises later in life when (1) a diagnosis with a genetic implication is made, (2) a couple is planning a family and there is a family history of a genetic problem, including whether one member of a couple carries a translocation or is a carrier of an abnormal gene for an autosomal recessive or X-linked disorder, (3) an adolescent or young adult has a family history of an adult-onset genetic disorder (e.g., Huntington disease or breast cancer), (4) unusual features are present and a diagnosis is wanting or not possible, or (5) there is suspected exposure to a toxic substance or teratogen. It is often necessary to have several meetings with a family in this third category. Urgency is not as much of an issue as being sure that they have as much

information and as many options as are available. All of the questions and concerns usually cannot be adequately addressed in one session.

GENETIC COUNSELING

Providing accurate information to families requires (1) taking a careful family history and constructing a pedigree that lists the patient's relatives (including abortions, stillbirths, and deceased individuals) with their sex, age, and state of health up to and including third-degree relatives; (2) gathering information from hospital records about the affected individual (and in some cases, about other family members); (3) documenting prenatal, pregnancy, and delivery histories; (4) reviewing the latest available medical, laboratory, and genetic information concerning the disorder; (5) careful physical examination of the affected individual (with photographs and measurements) and of apparently unaffected individuals in the family; (6) establishing or confirming the diagnosis by the diagnostic tests available; (7) giving the family information about support groups; (8) providing new information to the family as it becomes available (a mechanism for updating needs to be established).

To provide optimal benefits, the counseling session must include certain information:

The Specific Condition or Conditions.

If a specific diagnosis is made and confirmed, that should be discussed with the family and information provided in writing. However, often the disorder fits into a spectrum (e.g., 1 of 300 types of arthrogryposis) or the diagnosis is clinically rather than laboratory based. In those situations, the family needs to understand the limits of present knowledge and that additional research will probably lead to better information in the future.

Knowledge of the Diagnosis of the Particular Condition.

Although it is not always possible to make an exact diagnosis, having as accurate a diagnosis as possible is important. Estimates of recurrence risk for various family members depend on an accurate diagnosis. When a specific diagnosis cannot be made (as in many cases of multiple congenital anomalies), the various differential diagnoses should be discussed with the family and empirical information provided. If specific diagnostic tests are available, they should be discussed.

Natural History of the Condition.

It is very important to discuss the natural history of the specific genetic disorder in the family. Affected individuals and their families will have questions regarding the prognosis and potential therapy that can be answered only with knowledge of the natural history. If there are other possible differential diagnoses, their natural history may also be discussed. If the disorder is associated with a spectrum of clinical outcomes or complications, the worst and best scenario, as well as treatment and referral to the appropriate specialist, should be addressed.

Genetic Aspects of the Condition and Recurrence Risk.

This is important information for the family because all family members need to be aware of their reproductive choices. The genetics of the disorder can be explained with visual aids (e.g., figures of chromosomes). It is important to provide accurate occurrence and recurrence risks for various members of the family, including unaffected individuals, cousins, aunts, and so forth. In cases in which a definite diagnosis cannot be made, it is necessary to use empirical recurrence risks.

Counseling should give the individuals the necessary information to understand the various options and to make their own informed decisions regarding pregnancies, adoption, artificial insemination, prenatal diagnosis, screening, carrier detection, and termination of pregnancy. To complete this part of the educational process, it may be necessary to have more than one counseling session.

Prenatal Diagnosis and Prevention.

Many different methods of prenatal diagnosis are available, depending on the specific genetic disorder. The use of ultrasonography allows prenatal diagnosis of anatomic abnormalities such as congenital heart defects. Amniocentesis and chorionic villus sampling are used to obtain fetal tissue for analysis of chromosomal abnormalities, biochemical disorders, and DNA studies. Maternal blood or serum sampling is used for some types of screening. Fetal cells can be retrieved from the umbilical cord or from maternal blood for testing, although mothers may harbor cells from all previous pregnancies.

Therapies and Referral.

A number of genetic disorders require the care of a specialist. For example, individuals with Turner syndrome usually need to be evaluated by an endocrinologist. Prevention of known complications is a priority. The psychologic adjustment of the family may require specific intervention.

Support Groups.

A large number of community lay support groups have been formed to provide information and to fund research on specific genetic and nongenetic conditions. An important part of genetic counseling is to give information about these groups to individuals and to suggest a contact person for the families. Many groups have established websites with very helpful information.

Follow-up.

Families should be encouraged to continue to ask questions and keep up with new information about the specific disorder. New developments often influence the diagnosis and therapy of specific genetic disorders. Lay support groups are a good source of new information.

Nondirective Counseling.

In general, genetic counseling is nondirective. In most developed countries with modern health systems, choices about reproduction are left to the family to decide what is right for them. The role of the counselor (physician, genetic counselor, nurse, medical geneticist) is to provide information in understandable terms and outline the range of options available.

Part 10 - Metabolic Diseases

397

Chapter 73 - An Approach to Inborn Errors of Metabolism

Iraj Rezvani

Many childhood conditions are caused by gene mutations that encode specific proteins. These mutations can result in the alteration of primary protein structure or the amount of protein synthesized. The functional ability of protein, whether it is an enzyme, receptor, transport vehicle, membrane, or structural element, may be relatively or seriously compromised. These hereditary biochemical disorders are collectively termed *inborn errors of metabolism*.

Most mutations are clinically inconsequential and represent polymorphic differences that set individuals apart *(genetic polymorphism)*. However, some mutations produce disease states that range from very mild to lethal. Most inborn errors of metabolism exhibiting clinical consequences manifest in the newborn period or shortly thereafter.

It is both technologically and economically possible to screen for a large number of metabolic conditions during the first few days of life, before any clinical manifestations of the disease become apparent. Institution of early treatment often prevents the deleterious effects of these conditions, especially on the central nervous system. Intrauterine diagnosis of most genetic conditions is now feasible and is routinely used to detect affected fetuses in the population at risk (see Chapter 85).

Children with inborn errors of metabolism may present with one or more of a large variety of signs and symptoms. These may include high or normal anion gap metabolic acidosis, persistent vomiting, failure to thrive, altered consciousness, seizures, myopathy, developmental delay, hypoglycemia, elevated blood or urinary levels of a particular metabolite (an amino acid, organic acid, or ammonia), a peculiar odor (Table 73–1), or physical changes such as dysmorphology, cardiomegaly, rashes, cataracts, retinitis, optic atrophy, corneal opacity, deafness, skeletal dysplasias, macrocephaly, or hepatomegaly with or without hepatic failure, jaundice, or cirrhosis. Diagnosis is facilitated by considering those disorders presenting in the neonatal period separately from those presenting later in life.

Neonatal Period.

Inborn errors of metabolism causing *clinical manifestations* in the neonatal period are usually severe and are often lethal if proper therapy is not promptly initiated. Clinical findings are usually nonspecific and similar to those seen in infants with sepsis. An inborn error of metabolism should be considered in the differential diagnosis of a severely ill neonatal infant, and special studies should be undertaken if the index of suspicion is high (Fig. 73–1).

Infants with metabolic disorders are usually normal at birth; however, signs and symptoms such as lethargy, poor feeding, convulsions, and vomiting may develop as early as a few hours after birth. A history of clinical deterioration in a previously normal neonate should suggest an inborn error of metabolism. This clinical course contrasts to many other genetic disorders or perinatal insults, which cause abnormalities from the time of birth. Occasionally (urea cycle defects, organic acidurias, fatty acid oxidation disorders), vomiting may be severe enough to suggest the diagnosis of pyloric stenosis, which is usually not present, although it has simultaneously occurred in such infants. Lethargy, poor feeding, convulsions, and coma may also be seen in infants with hypoglycemia (see Chapters 81 and 96) or hypocalcemia (see Chapter 45.5). Measurements of blood concentrations of glucose and calcium and response to intravenous injection of glucose or calcium usually establish these diagnoses. Because most inborn errors of metabolism are inherited as autosomal recessive traits, a history of consanguinity and/or death in the neonatal period should increase suspicion of this diagnosis. Some of these disorders have a high incidence in specific population groups. For instance, tyrosinemia type 1 is more common among French Canadians of Quebec than in the general population. Therefore, knowledge of the ethnic background of the patient may be helpful in diagnosis. *Physical examination* usually reveals nonspecific findings, with most signs related to the central nervous system. Hepatomegaly, however, is a common finding in a variety of inborn errors of metabolism. Occasionally, an unusual odor may offer an invaluable aid to the diagnosis (see Table 73–1). A physician caring for a sick infant should smell the patient and his or her excretions; for example, patients with maple syrup urine disease have the unmistakable odor of maple syrup in their urine and on their bodies.

Diagnosis usually requires a variety of specific *laboratory studies*. Measurements of serum concentrations of glucose, ammonia, bicarbonate, and pH are often very helpful in differentiating major causes of metabolic disorders (see Fig. 73–1). Elevation of blood ammonia levels is usually caused by defects in urea cycle enzymes. Infants with elevated blood ammonia levels commonly have normal serum pH and bicarbonate values; without measurement of blood ammonia they may remain undiagnosed and succumb to their disease. Elevation of serum ammonia levels, however, has also been observed in some infants with certain organic acidemias. These infants are severely acidotic because of accumulation of organic

acids in body fluids.

When blood ammonia, pH, and bicarbonate values are normal, other aminoacidopathies (e.g., hyperglycinemia) or galactosemia should be considered; galactosemic infants may also manifest hypoglycemia, cataracts, hepatomegaly, ascites, and jaundice.

Most inborn errors of metabolism presenting in the neonatal period are lethal if specific *treatment* is not initiated immediately. Specific diagnosis, even in an infant in whom death seems inevitable, is of great importance for genetic counseling of the family (see Chapter 72). Therefore, every effort should be made

TABLE 73-1 -- **Inborn Errors of Amino Acid Metabolism Associated with Abnormal Odor**

Inborn Error of Metabolism	Urine Odor
Glutaric acidemia (type II)	Sweaty feet, acrid
Hawkinsinuria	Swimming pool
Isovaleric acidemia	Sweaty feet, acrid
Maple syrup urine disease	Maple syrup
Hypermethioninemia	Boiled cabbage
Multiple carboxylase deficiency	Tomcat urine
Oasthouse urine disease	Hops-like
Phenylketonuria	Mousy or musty
Trimethylaminuria	Rotting fish
Tyrosinemia	Boiled cabbage, rancid butter

Figure 73-1 Clinical approach to a newborn infant with a suspected metabolic disorder. This schema is a guide to the elucidation of some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases.

to determine the diagnosis while the infant is alive; postmortem examination is usually not helpful. A specific diagnosis is facilitated by direct biochemical assays of metabolites or their metabolic by-products, or of an enzyme's function; by DNA analysis of the gene; by functional tests; by neuroradiology; and with biopsies or postmortem examinations. With tandem mass spectroscopy use in neonatal metabolic screening programs, many disorders are identified in the presymptomatic stage.

Children after the Neonatal Period.

Most inborn errors of metabolism that cause symptoms in the first few days of life exhibit milder variant forms that have a more insidious onset. These forms may escape detection during the neonatal period, and the diagnosis may be delayed for months or even years. Early clinical manifestations in children with these forms are commonly nonspecific and may be attributed to unidentified perinatal insults.

Clinical manifestations, such as mental retardation, motor deficits, developmental regression, convulsions, myopathy, recurrent emesis with coma and hepatic dysfunction, and cardiomyopathy are the most constant findings in older children. There may be an episodic or intermittent pattern, with episodes of acute clinical manifestations separated by periods of seemingly disease-free states. The episodes are usually triggered by stress or a nonspecific catabolic insult, such as an infection. The child may die during one of these acute attacks. An inborn error of metabolism should be considered in any child with one or more of the following manifestations: (1) unexplained mental retardation, developmental delay or regression, motor deficits, or convulsions; (2) unusual odor, particularly during an acute illness; (3) intermittent episodes of unexplained vomiting, acidosis, mental deterioration, or coma; (4) hepatomegaly; (5) renal stones; or (6) muscle weakness or cardiomyopathy.

Chapter 74 - Defects in Metabolism of Amino Acids

74.1 Phenylalanine

Iraj Rezvani

Phenylalanine is an essential amino acid. Dietary phenylalanine not utilized for protein synthesis is normally degraded by way of the tyrosine pathway (Fig. 74–1). Deficiency of the enzyme phenylalanine hydroxylase or of its cofactor tetrahydrobiopterin causes accumulation of phenylalanine in body fluids and the central nervous system (CNS). The severity of hyperphenylalaninemia depends on the degree of enzyme deficiency and may vary from very high plasma concentrations (>20?mg/dL, or >1200?µM, “classic PKU”) to mildly elevated levels (2–6?mg/dL or 120–360?µM). In affected infants with plasma concentrations over 20?mg/dL, excess phenylalanine is metabolized to phenylketones (phenylpyruvate and phenylacetate; see Fig. 74–1) that are excreted in the urine, giving rise to the term *phenylketonuria (PKU)*. These metabolites have no role in pathogenesis of CNS damage in patients with PKU, and their presence in body fluids simply signifies the severity of the condition. The brain is the main organ affected by hyperphenylalaninemia. The CNS damage in affected patients is caused by the elevated concentration of phenylalanine in brain tissue, which interferes with the transport of other

Figure 74.1-1 Pathways of phenylalanine and tyrosine metabolism. Inborn errors are depicted as bars crossing the reaction arrow(s). Pathways for synthesis of cofactor BH_4 are shown in purple. PKU* refers to defects of BH4 metabolism that affect the phenylalanine, tyrosine, and tryptophan hydroxylases. See Figures 74–2 and 74–4 . **Enzymes:** (1) phenylalanine hydroxylase; (2) carbinolamine dehydratase; (3) dihydropteridine reductase; (4) 6-pyruvoyltetrahydropterin synthase; (5) guanosine triphosphate (GTP) cyclohydrolase; (6) tyrosine aminotransferase; (7a) intramolecular rearrangement; (7 + 7a) 4-hydroxyphenylpyruvate dioxygenase; (8) Homogentisic acid dioxygenase; (9) maleylacetoacetate isomerase; (10) fumarylacetoacetate hydroxylase.

large neutral amino acids (tyrosine, tryptophan) into the brain. There are a few adults with classic PKU and normal intelligence who have never been treated with a phenylalanine-restricted diet. Phenylalanine content of the brain in these individuals was found to be close to that of normal subjects when studied by magnetic resonance spectroscopy (MRS) and imaging (MRI) techniques.

Classic PKU.

Severe hyperphenylalaninemia (plasma phenylalanine levels > 20?mg/dL), if untreated, invariably results in the development of signs and symptoms of classic PKU, except in rare occasions.

CLINICAL MANIFESTATIONS.

The affected infant is normal at birth. Mental retardation may develop gradually and may not be evident for the first few months. It is usually severe, and most patients require institutional care if the condition remains untreated. Vomiting, sometimes severe enough to be misdiagnosed as pyloric stenosis, may be an early symptom. Older untreated children become hyperactive with purposeless movements, rhythmic rocking, and athetosis.

On physical examination these infants are lighter in their complexion than unaffected siblings. Some may have a seborrheic or eczematoid rash, which is usually mild and disappears as the child grows older. These children have an unpleasant odor of phenylacetic acid, which has been described as musty or mousy. There are no consistent findings on neurologic examination. However, most infants are hypertonic with hyperactive deep tendon reflexes. About 25% of children have seizures, and more than 50% have electroencephalographic abnormalities. Microcephaly, prominent maxilla with widely spaced teeth, enamel hypoplasia, and growth retardation are other common findings in untreated children. The clinical manifestations of classic PKU are rarely seen in those countries in which neonatal screening programs for the detection of PKU are in effect.

Milder Forms of Hyperphenylalaninemia, Non-PKU Hyperphenylalaninemias.

In any screening program for PKU, a group of infants are identified in whom initial plasma concentrations of phenylalanine are above normal (2?mg/dL, 120?µM) but less than 20?mg/dL (1200?µM). These infants do not excrete phenylketones. Clinically, these infants may remain asymptomatic but progressive brain damage may occur gradually with age. These patients have milder deficiencies of phenylalanine hydroxylase or its cofactor tetrahydrobiopterin (BH_4) than those with classic PKU. Attempts have been made to classify these patients in different subgroups depending on the degree of hyperphenylalaninemia, but such a practice seems to have very little clinical or therapeutic advantage. As with classic PKU, deficiency of BH_4 should be investigated in all infants with milder forms of hyperphenylalaninemia (see later).

DIAGNOSIS.

Because of gradual development of clinical manifestations of hyperphenylalaninemia, early diagnosis can only be achieved by mass screening of

all newborn infants (see later). In infants with positive results from the screen for hyperphenylalaninemia, diagnosis should be confirmed by quantitative measurement of plasma phenylalanine. Identification and measurement of phenylketones in the urine has no place in any screening program. However, in countries and places where such programs are not in effect, identification of phenylketones in the urine by ferric chloride may offer a simple test for diagnosis of infants with developmental and neurologic abnormalities. Once the diagnosis of hyperphenylalaninemia is established, deficiency of cofactor (BH_4) should be ruled out in all affected infants with proper studies (see later).

NEONATAL SCREENING FOR HYPERPHENYLALANINEMIA.

Effective and relatively inexpensive methods for mass screening of newborn infants have been developed and are being used in the United States and several other countries. The bacterial inhibition assay of Guthrie, which was the first and still the most widely used method for the purpose, is being replaced by more precise and quantitative methods (fluorometric and tandem mass spectrometry). All these methods require a few drops of blood, which are placed on a filter paper and mailed to a central laboratory for assay. Blood phenylalanine in affected infants with PKU may rise to diagnostic levels as early as 4?hr after birth even in the absence of protein feeding. It is recommended, however, that the blood for screening be obtained in the first 24–48?hr of life after feeding protein to reduce the possibility of false-negative results, especially in the milder forms of the condition.

TREATMENT.

The goal of therapy is to reduce phenylalanine in the body; formulas low in or free of this amino acid are commercially available. The diet should be started as soon as diagnosis is established. It is generally accepted that infants with persistent plasma levels of phenylalanine over 6?mg/dL (360?µM) should be treated with a phenylalanine-restricted diet similar to that for classic PKU. No dietary restriction is currently recommended for infants whose phenylalanine levels are between 2–6?mg/dL. Plasma concentrations of phenylalanine in treated patients should be maintained as close to normal as possible. Because phenylalanine is not synthesized by the body, “overtreatment” may lead to phenylalanine deficiency manifested by lethargy, failure to thrive, anorexia, anemia, rashes, diarrhea, and even death; moreover, tyrosine becomes an essential amino acid in this disorder and its adequate intake must be ensured. Controversies exist regarding the “allowable” degree of residual hyperphenylalaninemia in treated patients. It is generally believed that plasma phenylalanine levels should be maintained between 2–6?mg/dL (120–360?µM) at least in the first 12 yr of life. The duration of diet therapy is also controversial. Discontinuation of therapy, even in adulthood, may cause deterioration of IQ and cognitive performance. The current recommendation is that all patients be kept on a phenylalanine-restricted diet for life.

Oral administration of the cofactor (BH_4) to patients with milder forms of hyperphenylalaninemia from phenylalanine hydroxylase deficiency may produce significant reductions in plasma phenylalanine levels. These children may be able to tolerate a less restricted diet (see later for BH_4 therapy). Dietary management of hyperphenylalaninemia requires close monitoring of blood levels of phenylalanine, expert nutritional input, and well-designed educational materials for the patient and the family. Proper management of these patients is best achieved through a regional treatment center.

PREGNANCY IN WOMEN WITH HYPERPHENYLALANINEMIA (MATERNAL PKU).

Pregnant women with hyperphenylalaninemia who are not receiving a phenylalanine-restricted diet carry a very high risk of having offspring with mental retardation, microcephaly, and congenital heart disease. These complications are related to high levels of maternal plasma phenylalanine during pregnancy. Prospective mothers who have been treated for hyperphenylalaninemia should be maintained on a phenylalanine-restricted diet before and during pregnancy, and every effort should be made to keep blood phenylalanine levels below 6?mg/dL (360?µM) throughout the pregnancy. All women with hyperphenylalaninemia who are of childbearing age should be counseled properly as to the risk of the just described congenital anomalies in their offspring.

Hyperphenylalaninemia from Deficiency of the Cofactor Tetrahydrobiopterin (BH_4).

In 1–2% of infants with hyperphenylalaninemia, the defect resides in one of the enzymes necessary for production or recycling of the cofactor BH_4 (Fig. 74–2). These infants are diagnosed as having PKU, but they deteriorate neurologically despite adequate control of plasma phenylalanine. BH_4 is the cofactor for phenylalanine, tyrosine, and tryptophan hydroxylases. The latter two hydroxylases are essential for biosynthesis of the neurotransmitters dopamine (see Fig. 74–2) and serotonin (see Fig. 74–5). BH_4 is also a cofactor for nitric oxide synthase, which catalyzes the generation of nitric oxide from arginine. Currently, patients with BH_4 deficiency are diagnosed very early in life because all patients with PKU and hyperphenylalaninemia are tested for the possibility of this cofactor deficiency.

BH_4 is synthesized from guanosine triphosphate through several enzymatic reactions (see Fig. 74–1). Four enzyme deficiencies leading to defective BH_4 formation have been described. More than half of the reported patients have had a deficiency of 6-pyruvoyltetrahydropterin synthase (PTPS).

CLINICAL MANIFESTATIONS.

Infants with cofactor deficiency are identified during screening programs for PKU because of evidence of hyperphenylalaninemia. Plasma phenylalanine levels may be as high as those in classic PKU or in the range of milder forms of hyperphenylalaninemia. Neurologic manifestations, such as loss of head control, truncal hypotonia (floppy baby), drooling, swallowing difficulties, and myoclonic seizures, develop after 3 mo of age despite adequate dietary therapy.

Figure 74.1-2 Other pathways involving tyrosine metabolism. PKU* indicates hyperphenylalaninemia due to tetrahydrobiopterin deficiency (see Fig. 74–1). **Enzymes:** (1) thyrosine hydroxylase; (2)

aromatic L-amino acid decarboxylase (AADC); (3) dopamine hydroxylase; (4) phenylethanolamine-*N*-methyltransferase (PNMT).

DIAGNOSIS.

BH_4 deficiency and the responsible enzyme defect may be diagnosed by performing any or all of the following tests:

1. Measurement of neopterin (oxidative product of dihydroneopterin triphosphate) and biopterin (oxidative product of dihydrobiopterin and tetrahydrobiopterin) in body fluids, especially urine (see Fig. 74–1). In patients with guanosine triphosphate (GTP) cyclohydrolase deficiency, urinary excretion of both neopterin and biopterin is very low. In patients with 6-pyruvoyltetrahydropterin synthase deficiency, there is a marked elevation of neopterin excretion and a concomitant decrease in biopterin excretion. In patients with dihydropteridine reductase deficiency, the neopterin excretion is normal but that of biopterin is very high. Excretion of biopterin increases in this enzyme deficiency because the quinonoid dihydrobiopterin cannot be recycled into BH_4 . Patients with carbinolamine dehydratase deficiency excrete 7-biopterin (an unusual isomer of biopterin) in their urine.
2. BH_4 loading test. An oral dose of BH_4 (20?mg/kg) normalizes plasma phenylalanine in patients with BH_4 deficiency within 4–8?hr. The blood phenylalanine level should be elevated (>400?µM) to be able to interpret the results. This may be achieved by discontinuing diet therapy for 2 days before the test or by administering a loading dose of phenylalanine (100?mg/kg) 3?hr before the BH_4 test.
3. Enzyme assay. The activity of dihydropteridine reductase can be measured in the dry blood spots on the filter paper used for screening purposes. 6-Pyruvoyltetrahydropterin synthase activity can be measured in the liver, kidneys, and erythrocytes. Carbinolamine dehydratase activity can be measured in the liver and kidneys. GTP cyclohydrolase activity can be measured in the liver and in cytokine (interferon ?)-stimulated mononuclear cells or fibroblasts (the enzyme activity is normally very low in unstimulated cells).

TREATMENT.

The goals of therapy are to correct hyperphenylalaninemia and to restore neurotransmitter deficiencies in the CNS.

1. The control of hyperphenylalaninemia is important in patients with cofactor deficiency, because high levels of phenylalanine interfere with the transport of neurotransmitter precursors (tyrosine and tryptophan) into the brain tissue. Plasma phenylalanine should be maintained as close to normal as possible (<6?mg/dL). This can be achieved by a combination of a low-phenylalanine diet and oral supplementation of BH_4 . Infants with GTP cyclohydrolase or PTPS deficiencies respond more readily to BH_4 therapy (5–10?mg/kg/day) than those with dihydropteridine reductase deficiency. In the latter patients, doses as high as 20?mg/kg/day may be required. BH4 for replacement therapy is commercially available although it remains quite expensive.
2. Administration of deficient neurotransmitters, namely L-dopa and 5-hydroxytryptophan, is recommended even when treatment with BH_4 normalizes plasma levels of phenylalanine. BH_4 does not readily enter the brain tissue to restore local neurotransmitter production. Supplementation with folinic acid is also recommended in patients with dihydropteridine reductase deficiency.

Hyperprolactinemia occurs in patients with BH_4 deficiency and may be due to dopamine deficiency (which is the major prolactin-inhibiting factor) in the hypothalamic region. Measurement of serum prolactin levels may be a convenient method to monitor adequacy of neurotransmitter replacement in affected patients.

Some drugs such as trimethoprim sulfamethoxazole, methotrexate, and other antileukemic agents are known to inhibit dihydropteridine reductase enzyme activity and should be used with great caution in patients with BH_4 deficiency.

GENETICS AND PREVALENCE.

All defects causing hyperphenylalaninemia are inherited as autosomal recessive traits. The prevalence of PKU in the United States is estimated at 1:14,000 to 1:20,000 live births. The prevalence of non-PKU hyperphenylalaninemia is estimated at 1:50,000. The condition is more common in whites and Native Americans and less prevalent in blacks, Hispanics, and Asians. The gene for phenylalanine hydroxylase is located on chromosome 12q22-q24.1, and over 400 different disease-causing mutations have been identified in different families. The majority of patients are compound heterozygotes for two different mutant alleles.

Genes for all enzymes involved in biosynthesis of BH_4 have been identified and, as with the phenylalanine hydroxylase gene, many mutations have been identified in different families. The gene for PTP synthase, the most common cause of BH_4 deficiency, resides on chromosome 11q22.3-22.3, the gene for dihydropteridine reductase is located on chromosome 4p15.3, and those of carbinolamine dehydratase and GTP cyclohydrolase are on 10q22 and 17q22.1-22.2, respectively. *Prenatal diagnosis* is possible using specific genetic probes in cells obtained from chorionic villi biopsy.

Tetrahydrobiopterin Defects without Hyperphenylalaninemia

HEREDITARY PROGRESSIVE DYSTONIA, AUTOSOMAL DOMINANT DOPA-RESPONSIVE DYSTONIA, SEGAWA SYNDROME (also see chapter 590.3).

This rare form of dystonia, first described in Japan, has been shown to be caused by GTP cyclohydrolase deficiency. It is inherited as an autosomal dominant trait and is more common in females than males (4:1).

Clinical manifestations usually occur around 5–6 yr of age and are heralded by

dystonia of the lower limbs, which may spread to all extremities within a few years. Torticollis, dystonia of the arms, and poor coordination may precede dystonia of the lower limbs in some patients. Early development is generally normal. The symptoms usually have an impressive diurnal variation, becoming worse by the end of the day and improving with sleep. Parkinsonian signs may also be present or develop subsequently with advancing age. Patients may be misdiagnosed as having cerebral palsy. Late presentation in adult life has also been reported.

Laboratory findings show no hyperphenylalaninemia, but reduced levels of BH_4 and neopterin are found in the spinal fluid. Dopamine and its metabolites (homovanillic acid) may also be reduced in the spinal fluid. It is believed that the enzyme deficiency in this condition is less severe than that of the autosomal recessive form of GTP cychlohydrolase deficiency, which is associated with hyperphenylalaninemia. The existence of asymptomatic carriers indicates that other factors or genes may play a role in pathogenesis of the phenotype.

Diagnosis may be confirmed by reduced levels of BH_4 and neopterin in the spinal fluid, by measurement of the enzyme activity (see earlier), and by identification of the gene defect. Clinically, the condition should be differentiated from other causes of dystonias and childhood parkinsonism, especially tyrosine hydroxylase (see Chapter 74.2) and aromatic amino acid decarboxylase deficiencies. The striking diurnal pattern of dystonia is an important clinical finding in favor of GTP cyclohydrolase deficiency.

*Treatment w*ith L-dopa in conjunction with a peripheral dopa decarboxylase inhibitor usually produces dramatic improvement.

74.2 Tyrosine

Iraj Rezvani

Tyrosine, obtained from ingested proteins and synthesized endogenously from phenylalanine, is used for protein synthesis and is a precursor of dopamine, norepinephrine, epinephrine, melanin, and thyroxine. Excess tyrosine is metabolized to carbon dioxide and water (see Fig. 74–1). Hypertyrosinemia is observed with deficiencies of tyrosine aminotransferase, 4-hydroxyphenpyruvate dioxygenase (4-HPPD), or fumarylacetoacetate hydrolase (FAH). The causal relationship of high levels of tyrosine with the diseased state has been established only in deficiency of tyrosine aminotransferase (tyrosinemia type II). The significance of hypertyrosinemia in the pathogenesis of the other two enzyme deficiencies is unclear.

Deficiencies of other enzymes involved in tyrosine degradation cause little or no increase in blood levels of tyrosine. *Acquired hypertyrosinemia* may occur in conditions such as severe hepatocellular dysfunction (liver failure), scurvy (vitamin C is the cofactor of 4-HPPD enzyme), and hyperthyroidism.

Tyrosinemia Type I (Tyrosinosis, Hereditary Tyrosinemia, Hepatorenal Tyrosinemia).

In this condition, caused by a deficiency of the enzyme fumarylacetoacetate hydrolase, a moderate elevation of serum tyrosine is associated with severe involvement of the liver, kidneys, and central nervous system. These findings are thought to be due to accumulation of intermediate metabolites of tyrosine in the body, especially succinylacetone.

CLINICAL MANIFESTATIONS.

The clinical description is based on patients of French-Canadian descent, who have a more severe form of the disease than other ethnic groups.

The affected infant may become symptomatic as early as 2 wk of age or may remain seemingly healthy during the first yr of life. The earlier the presentation, the poorer is the prognosis. The 1-yr mortality, which is about 60% in infants who develop symptoms before 2 mo of age, decreases to 4% in infants who become symptomatic after 6 mo of age.

The major organs affected are the liver, peripheral nerves, and kidneys. An acute *hepatic crisis* commonly heralds the onset of the disease and is usually precipitated by an intercurrent illness that produces a catabolic state. Fever, irritability, vomiting, hemorrhage (melena, hematemesis, hematuria), hepatomegaly, jaundice, elevated

levels of serum transaminases, and hypoglycemia are common. An odor resembling boiled cabbage may be present and may be due to increased methionine metabolites. Most hepatic crises resolve spontaneously, but progression to liver failure and death may occur. Between the crises, varying degrees of failure to thrive, hepatomegaly, and coagulation abnormalities often persist. Cirrhosis of the liver and eventually hepatocellular carcinoma occur in children who survive beyond 2 yr. The incidence of hepatic carcinoma may be as high as 37%.

Episodes of acute *peripheral neuropathy* resembling acute porphyria occur in about 40% of affected children. These crises, often triggered by a minor infection, are characterized by severe pain, often in the legs, associated with hypertonia (causing hyperextension of the trunk and neck), vomiting, paralytic ileus, and, occasionally, self-induced injuries. Marked weakness and paralysis occur in about 30% of the episodes, which may lead to respiratory failure and death. These crises may last 1–7 days. Urinary excretion of 5-aminolevulinic acid, which is usually elevated before the crises (see later), is further increased during the episodes. Monitoring the urinary excretion of this compound has little diagnostic or predictive value.

Renal involvement is manifested as a Fanconi-like syndrome with a normal anion gap metabolic acidosis, hyperphosphaturia, hypophosphatemia, and vitamin D–resistant rickets. Nephromegaly and some degree of nephrocalcinosis are often found by ultrasound examination of the kidneys.

Hypertrophic cardiomyopathy is occasionally seen in these infants.

LABORATORY FINDINGS.

These include normocytic anemia and marked elevations of serum bilirubin (both conjugated and unconjugated), serum transaminases, and a-fetoprotein. An increase in serum levels of a-fetoprotein is observed in the cord blood of affected infants, indicating intrauterine liver damage. Clotting factors are often markedly decreased. Plasma levels of tyrosine and other amino acids, especially methionine (presumably due to secondary inhibition of methionine adenosyltransferase), are moderately increased. Generalized aminoaciduria occurs. Hyperphosphaturia and hypophosphatemia are common. Urinary excretion of 5-aminolevulinic acid (presumably due to inhibition of 5-aminolevulinic hydratase by succinylacetone) may be increased. The presence of succinylacetoacetate and succinylacetone in serum and urine is diagnostic (see Fig. 74–1). Liver histology is usually compatible with chronic hepatitis and nonspecific cirrhosis. Hyperplasia of pancreatic islet cells is also found.

Diagnosis is established by measurement of fumarylacetoacetate hydroxylase activity in lymphocytes, erythrocytes, and liver biopsy specimens. The degree of residual enzyme activity usually dictates the severity of the disease. This condition should be differentiated from other causes of hepatitis and hepatic failure in infants, including galactosemia, hereditary fructose intolerance, neonatal iron storage disease, biliary atresia, and giant cell hepatitis.

TREATMENT AND OUTCOME.

A diet low in phenylalanine and tyrosine may result in some clinical improvement in some

patients. However, in most affected infants the progression of the disease cannot be halted by diet alone. Inhibition of the enzyme 4-hydroxyphenylpyruvate dioxygenase by 2-(nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) is a very effective treatment. Acute hepatic and neurologic crises do not occur in patients treated with this agent. Long-term efficacy of NTBC in prevention of hepatic carcinoma, although it seems very promising, awaits further data. It is recommended that patients receive a diet low in phenylalanine and tyrosine in addition to NTBC therapy. Liver transplantation has been considered the most effective therapy for these patients. Whether treatment with NTBC alleviates or delays the need for liver transplantation remains to be determined.

GENETICS AND PREVALENCE.

Tyrosinemia type I is an autosomal recessive trait. The *gene* for fumarylacetoacetate hydrolase has been mapped to the long arm of chromosome 15. Over 30 different mutations have been identified in different families. Most reported patients have a French-Canadian or Scandinavian ancestry. The prevalence of the condition is estimated to be 1 in 1,846 live births in the Saguenay-Lac Saint Jean region of the province of Quebec (Canada). The worldwide prevalence is estimated to be 1:100,000 to 1:120,000. *Prenatal diagnosis* has been achieved by measurement of succinylacetone in amniotic fluid and by the enzyme assay in chorionic villi biopsy. Direct gene analysis is possible in some families.

Tyrosinemia Type II (Richner-Hanhart Syndrome, Oculocutaneous Tyrosinemia).

This rare autosomal recessive disorder results in palmar and plantar punctate hyperkeratosis, herpetiform corneal ulcers, and mental retardation. *Clinical manifestations* of excessive tearing, redness, pain, and photophobia may occur before skin lesions. Corneal lesions usually occur during the first few months of life and are presumed to be due to tyrosine deposition. Skin lesions, which may develop later in life, include painful, nonpruritic hyperkeratotic plaques on the soles, palms (especially thenar and hypothenar areas), and fingertips. Mental retardation, which occurs in less than 50% of patients, is usually mild to moderate and may be associated with self-mutilation.

Abnormal *laboratory findings* are limited to significant hypertyrosinemia (20–50?mg/dL) and tyrosinuria. The condition is caused by the deficiency of the cytosolic fraction of hepatic tyrosine aminotransferase. In contrast to tyrosinemia type I, liver and kidney functions, as well as serum concentrations of other amino acids, are normal.

Treatment with a diet low in tyrosine and phenylalanine corrects the chemical abnormalities and results in dramatic healing of the skin and eye lesions. Mental retardation may be prevented by early dietary restriction of tyrosine. The gene for tyrosine aminotransferase is located on the long arm of chromosome 16; about 15

different mutations are identified in different families. About half the reported cases are of Italian descent.

Tyrosinemia Type III (Primary Deficiency of 4-Hydroxyphenylpyruvate Dioxygenase, 4-HPPD).

Only four cases have been reported. All patients have various neurologic findings but no consistent clinical phenotype. There is doubt as to whether this enzyme deficiency causes any clinical abnormalities. Age at onset has been from 1–17 mo. Developmental delay, seizures, intermittent ataxia, and self-destructive behavior have been the main neurologic findings. No liver or renal abnormalities are present.

The *diagnosis* is established by moderate increases in plasma levels of tyrosine (350–700?µM), the presence of 4-hydroxyphenylpyruvic acid and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids) in urine, and low activity of 4-HPPD enzyme in liver biopsy.

Diets low in tyrosine and phenylalanine in combination with vitamin C cause a dramatic decrease in plasma tyrosine levels. The beneficial effects of the diet on neurologic abnormalities have not been demonstrated. The mode of inheritance is not known.

Transient Tyrosinemia of the Newborn.

In a small number of newborn infants, plasma tyrosine may rise to as high as 60?mg/dL during the first 2 wk of life. Most affected infants are premature and are receiving high-protein diets. The condition is presumably due to delayed maturation of 4-hydroxyphenylpyruvate dioxygenase. Lethargy, poor feeding, and decreased motor activity occur in some of them, but most are asymptomatic and come to medical attention because of a high blood phenylalanine level, from the screening test for PKU. *Laboratory findings* include marked elevation of plasma tyrosine with a moderate increase in plasma phenylalanine. The presence of marked hypertyrosinemia differentiates this condition from phenylketonuria. Four-hydroxyphenylpyruvic acid and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids) are also present in the urine. Hypertyrosinemia usually resolves spontaneously during the 1st mo of life. The condition is often corrected promptly by reducing the amount of protein in the diet (to 2?g/kg/24?hr) and by administering vitamin C (200–400?mg/24?hr). Mild intellectual deficits have been reported in some full-term infants with this disorder, but the causal relationship to hypertyrosinemia has not been established.

Hawkinsinuria.

This rare condition (named after the first affected family) is caused by a deficiency of one of the components of the 4-hydroxyphenylpyruvate dioxygenase enzyme complex (see Fig. 74–1). A block in the rearrangement step leads to an accumulation of the epoxide intermediate, which either is reduced to form 4-hydroxycyclohexylacetic acid (4-HCAA) or reacts with glutathione to form the unusual organic acid hawkinsin (2-L-cysteine-S-yl-1-4-dihydroxycyclohex-5-en-1-yl-acetic acid); secondary glutathione deficiency may occur.

Individuals with this disorder become symptomatic only during infancy. The symptoms usually appear after weaning from breast-feeding with the introduction of a high-protein diet. Severe metabolic acidosis, ketosis, failure to thrive, mild hepatomegaly, and an unusual odor (of a swimming pool) are common findings. These infants respond well to a diet low in both phenylalanine and tyrosine, and their clinical manifestations resolve spontaneously by 1 yr of age. Adults with this condition are usually asymptomatic despite metabolic abnormalities. Mental development is usually normal.

Affected children and adults excrete 4-hydroxyphenylpyruvic acid and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids) as well as 5-oxoproline (owing to secondary glutathione deficiency) and the two very unusual organic acids 4-HCAA and hawkinsin in their urine. One patient had mild hypertyrosinemia (196?µM).

Treatment consists of a low-protein diet (such as breast milk) or a diet low in phenylalanine and tyrosine. Large doses of vitamin C (up to 1,000?mg/24?hr) are recommended. No therapy is needed after 1 yr of age. The condition is inherited as an autosomal dominant trait; all patients are presumed to be heterozygous. The gene has not yet been identified.

Alcaptonuria.

This rare (incidence about 1 in 250,000) autosomal recessive disorder is caused by a deficiency of homogentisic acid oxidase, which causes large amounts of homogentisic acid to accumulate in the body and then to be excreted in the urine (see Fig. 74–1). It is most common in the Dominican Republic and Slovakia.

Clinical manifestations consist of ochronosis and arthritis. These findings may not become evident until mid-adult life. The only sign of the disorder in the pediatric age group is a darkening of the urine to almost a black color on standing. This is caused by oxidation and polymerization of the homogentisic acid and is enhanced with an alkaline pH. Therefore, acid urine may not become dark even after many hours of standing. This is one of the reasons why darkening of the urine may never be noted in an affected person, and the diagnosis may be delayed until adulthood, when arthritis or ochronosis occurs. *Ochronosis*, a

---

term used to describe the darkening of tissue, is due to a slow accumulation of the black polymer of homogentisic acid in cartilage and other mesenchymal tissues. It is manifested clinically as dark, blackened spots in the sclera or as diffuse blackish pigmentation of the conjunctiva, cornea, and ear cartilage. *Arthritis* is the only disabling effect, which occurs in almost all affected subjects with advancing age. It involves the large joints (spine, hip, and knee) and is usually more severe in male patients. The arthritis has the clinical characteristics of rheumatoid arthritis, but the radiologic findings are typical of osteoarthritis. Degenerative changes in the lumbar spine are quite characteristic with narrowing of the joint spaces and fusion of the vertebral bodies. The pathogenesis of arthritic changes is unclear. High incidences of

heart disease (mitral and aortic valvulitis, calcification of the heart valves, and myocardial infarction) have also been noted.

The *diagnosis* is confirmed by measurement of homogentisic acid in urine. Affected subjects may excrete as much as 4–8?g of this compound daily. Homogentisic acid is a strong reducing agent that produces a positive reaction with Fehling or Benedict reagent (but not with glucose oxidase). The dark urine of phenol poisoning and that associated with melanotic tumors do not have these reducing properties. The enzyme is expressed only in the liver and kidneys. The gene for alcaptonuria has been mapped to the long arm of chromosome 3 and several disease-causing mutations have been identified.

There is no effective *treatment* for this disorder. Nitisinone inhibits homogentisate production; its long term efficacy is unknown.

Tyrosine Hydroxylase Deficiency (Infantile Parkinsonism, Autosomal Recessive Dopa Responsive Dystonia) (see Chapter 590.3).

This enzyme catalyzes the formation of L-dopa from tyrosine (see Fig. 74–2). Deficiency of this enzyme is seen in a few children with dystonia and parkinsonism. The clinical picture resembles the autosomal dominant dystonia that is due to GTP cyclohydrolase deficiency (see Chapter 74.1). The spectrum of the condition is not fully appreciated.

Clinical manifestations such as jerky movements of the limbs leading to spasticity and muscle rigidity, expressionless face, ptosis, drooling, oculogyric crises, and parkinsonism may start in early infancy. Psychomotor retardation has been seen in some patients. No diurnal variation of the symptoms has been noted.

Laboratory findings include reduced levels of dopamine and its metabolite HVA (homovanillic acid) and normal concentrations of BH4 and neopterin in the spinal fluid. Serum prolactin levels are usually elevated.

Diagnosis should be considered in any patients with dystonia and parkinsonism. GTP cyclohydroxylase deficiency should be ruled out by proper studies (see earlier). Diagnosis is established by the laboratory findings (see earlier) and gene analysis.

Treatment with L-dopa results in a dramatic response. The condition is inherited as an autosomal recessive trait. The gene for tyrosine hydroxylase is mapped to chromosome 11p.

Albinism.

Albinism is caused by defects in the biosynthesis and distribution of melanin. Melanin is synthesized by melanocytes from tyrosine in a membrane-bound intracellular organelle, the melanosome. Melanocytes originate from the embryonic neural crest and migrate to the skin, eyes (choroid and iris), and hair follicles. The melanin in the eye is not secreted into the adjacent tissues, whereas the pigment in skin and hair follicles is secreted into the epidermis and the hair shaft. The rate of melanogenesis is very low in the eye and very high in the skin and hair. The biosynthetic pathway for melanin synthesis is not completely elucidated (see Fig. 74–2). The end products are two pigments *pheomelanin*, which is a yellow-red pigment, and *eumelanin*, a brown-black pigment.

Clinical manifestations common in generalized albinism are hypopigmentation of the skin and hair. Patients with involvement of the eyes may have strabismus, photophobia, decreased visual acuity, and the presence of red reflex. Irides are translucent and pink in infancy and change to light blue or brown with age. Biocular (stereoscopic) vision is absent because of an abnormal decussation and misrouting of the optic fibers at the chiasm. About 90% of optic nerve fibers from one eye cross to the other side at the chiasma in patients with albinism. This defect also causes asymmetric visual evoked potentials. Blindness and skin cancer are major late sequelae of albinism in its severe forms. Melanin is also present in the cochlea. Albino individuals may be more susceptible to ototoxic agents such as gentamicin.

Many clinical forms of albinism have been identified. Some of the seemingly distinct clinical forms are caused by different mutations of the same gene. Several genes (mostly autosomal recessive, rarely autosomal dominant) and at least one on the short arm of the X chromosome have been found to be involved in melanogenesis (Table 74–1). Attempts to differentiate types of albinism based on the mode of inheritance, tyrosinase activity, or the extent of hypopigmentation have failed to yield a comprehensive classification. The following classification is based on the distribution of albinism in the body and the type of mutated gene.

OCULOCUTANEOUS (GENERALIZED) ALBINISM (OCA).

Lack of pigment is generalized, affecting skin, hair, and eyes. Three genetically distinct forms exist: OCA_1 , OCA_2 , and OCA_3 . The lack of pigment is usually more severe in patients with OCA_1 , however; these types may not be distinguishable clinically because of a great degree of overlap. All are inherited as autosomal recessive traits.

OCA_1 (Tyrosinase-Deficient Albinism). The defect resides in the tyrosinase gene, located on the long arm of chromosome 11. Many mutant alleles have been identified. Most affected individuals are compound heterozygote for two different mutant alleles. The condition can be subdivided to OCA_1 A and OCA_1 B based on enzyme activity and, to a lesser extent, clinical manifestations.

OCA_1 A (Tyrosinase-Negative OCA). A number of mutations in the tyrosinase gene render the enzyme completely inactive. Individuals with this form usually have the most severe case of generalized albinism. Lack of pigment in the skin (milky white), hair (white hair), and eyes (red-gray irides) is evident at birth and remains unchanged throughout life. They do not tan and do not develop pigmented nevi or freckles.

OCA_1 B. These mutations in the tyrosinase gene result in enzymes with some residual activities. These individuals, although

TABLE 74.2-1 -- **Classification of Albinism**

Type	Gene	Chromosome

Oculocutaneous Albinism (OCA)		
OCA_1 (tyrosinase deficient)	*TYR*	11_q
OCA_1 A (severe deficiency)	*TYR*	11_q
OCA_1 B (mild deficiency)[*]	*TYR*	11_q
OCA_2 (tyrosinase positive)[†]	*p* (pink-eyed dilution)	15_q

† *Includes brown OCA.*
‡ *Tyrosinase-related protein 1.*

completely depigmented at birth, are capable of developing some pigment with age and become light blond with light blue or hazel eyes. They develop pigmented nevi and freckles and they may tan. These patients, depending on the degree of pigmentation, were once subdivided into different groups and were thought to be genetically different. One interesting form is temperature-sensitive albinism in which the tyrosinase becomes more active in cooler parts of the body such as limbs. These individuals have no pigment in the scalp and trunk but develop some pigment in arms and legs.

OCA_2 (Tyrosinase-Positive Albinism). This is the most common form of generalized albinism and is particularly common in African blacks. Patients demonstrate some pigmentation of the skin and eyes at birth and continue to collect pigment throughout their lives. The hair is yellow at birth and may become darker with age. They have pigmented nevi and freckles, but they do not tan. They may be clinically indistinguishable from OCA_1 B. These individuals have normal tyrosinase activity. The defect is in the *p* (pink-eyed dilution) gene, located on the long arm of chromosome 15. This gene produces the p protein, a melanosome membrane protein the function of which is not completely understood. Patients with *Prader-Willi* and *Angelman* syndromes who have deletion of chromosome 15 have this form of albinism (see Chapter 69).

OCA_3 (Rufous Albinism). This form has been identified only in Africans, African-Americans, and natives of New Guinea. Patients have reddish hair with reddish brown skin as an adult. The color of the skin is peculiar to this form. As a youngster the manifestations may be confused with those of OCA_2 . These patients can make pheomelanin but not eumelanin. The mutation is in the tyrosinase-related protein 1 *(TYRP1)* gene, whose function is not understood.

HERMANSKY-PUDLAK SYNDROME.

This tyrosinase-positive oculocutaneous albinism is associated with platelet dysfunction (owing to the absence of platelet-dense bodies) and an accumulation of a ceroid-like material in tissues. The degree of albinism is variable. The condition is most prevalent in Puerto Rico (frequency about 1:2,000). Bleeding tendencies, often manifested as epistaxis and a prolonged bleeding time, are common. The ceroid-like material is histochemically similar to that found in neuronal ceroid-lipofuscinosis. The accumulation of this material in tissues results in restrictive lung disease, inflammatory bowel disease, kidney failure, and cardiomyopathy during the third or fourth decade of life. The condition is caused by mutations in one of the two genes, *HPS1* or *HPS2*. The majority of patients have mutations in *HPS1*, which is located on chromosome 10q. The pathogenesis is not understood.

CHÉDIAK-HIGASHI SYNDROME.

Patients with this rare autosomal recessive condition have partial albinism and susceptibility to infection with the presence of giant peroxidase-positive lysosomal granules in granulocytes (see Chapter 120.3). These patients have a reduced number of melanosomes, which are abnormally large (macromelanosomes). Patients who survive early childhood may develop a lymphoproliferative malignancy. Mutations in *CHS1* gene (located on the long arm of chromosome 1) have been identified in these patients.

OCULAR ALBINISM (OA).

Albinism is limited to the eyes. All the eye findings of albinism (see earlier) are present. The X-linked recessive form (OA_1) has been segregated as a separate entity. Autosomal recessive ocular albinism is a mild variant of OCA_2.

Ocular Albinism 1 (OA_1 Nettleship-Falls Type). Only the hemizygote male has the complete manifestation while some abnormal retinal pigmentation may be present in heterozygote female carriers. The gene is located on the short arm of the X chromosome. An X-linked ocular albinism with late-onset sensorineural deafness has also been reported.

LOCALIZED ALBINISM.

This disorder is characterized by localized hypopigmentation of skin and hair, which may be present at birth or develop with time.

Piebaldism. In this autosomal dominant inherited condition, the individual is usually born with a white forelock. The underlying skin is depigmented. There are usually white macules on the face, trunk, and extremities. The white hair lock and the depigmented underlying skin are devoid of melanocytes. Mutations in the *KIT* gene have been shown in affected patients.

Waardenburg Syndrome. In this syndrome, lateral displacement of inner canthi, broad nasal bridge, heterochromia of irides, and sensorineural deafness are associated with a white forelock. It is inherited as an autosomal dominant trait with four identifiable types. Type I has displacement of inner canthi and is caused by mutations in the *PAX3* gene. Type II has normal inner canthi and mutations in the *MITF* gene in some patients. Type III has all the findings seen in individuals with type I plus hypoplasia and contractures of the upper limbs. The gene abnormality is in *PAX3*. Type IV is associated with Hirschsprung disease and is heterogeneous with mutations in different genes *(EDN3, EDNRB,* or *SOX10).*

74.3 Methionine

Iraj Rezvani
David S. Rosenblatt

The normal pathway for catabolism of methionine, an essential amino acid, produces *S*-adenosylmethionine (which serves as a methyl group donor for methylation of a variety of compounds in the body), and cysteine, which is formed through a series of reactions called *trans*-sulfuration (Fig. 74–3).

Homocystinuria (Homocystinemia).

Most homocysteine, an intermediate compound of methionine degradation, is normally remethylated to methionine. This methionine-sparing reaction is catalyzed by the enzyme methionine synthase, which requires a metabolite of folic acid (5-methyltetrahydrofolate) as a methyl donor and a metabolite of vitamin B_{12} (methylcobalamin) as a cofactor (see Fig. 74–3). Only 20–30% of total homocysteine (and its dimer homocystine) is in free form in the plasma of normal individuals. The rest is bound to protein. Three major forms of homocystinemia and homocystinuria have been identified.

HOMOCYSTINURIA DUE TO CYSTATHIONINE SYNTHASE DEFICIENCY (CLASSIC HOMOCYSTINURIA).

This is the most common inborn error of methionine metabolism. About 40% of affected patients respond to high doses of vitamin B_6 and usually have milder clinical manifestations than those who are unresponsive to vitamin B_6 therapy. These patients possess some residual enzyme activity.

Infants with this disorder are normal at birth. *Clinical manifestations* during infancy are nonspecific and may include failure to thrive and developmental delay. The diagnosis is usually made after 3 yr of age, when subluxation of the ocular lens *(ectopia lentis)* occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive *mental retardation* is common. Normal intelligence, however, has been reported. In an international survey of over 600 patients, IQ scores ranged from 10 to 135. The higher IQ scores were noted in vitamin B_6 responsive patients. *Psychiatric and behavioral disorders* have been observed in more than 50% of affected patients. Convulsions occur in about 20% of patients. Affected individuals with homocystinuria manifest *skeletal abnormalities* resembling those of Marfan syndrome (see Chapter 690); they are usually tall and thin with elongated limbs and arachnodactyly. Scoliosis, pectus excavatum or

carinum, genu valgum, pes cavus, high arched palate, and crowding of the teeth are common. Patients usually have fair complexions, blue eyes, and a peculiar malar flush. Generalized osteoporosis, especially of the spine, is the main radiographic finding. *Thromboembolic episodes* involving both large and small vessels, especially those of the brain, are common and may occur at any age. Optic atrophy, paralysis, cor pulmonale, and

Figure 74.3-3 Pathways in the metabolism of the sulfur-containing amino acids. **Enzymes:** (1) methionine adenosyltransferase; (2) adenosylhomocysteine hydrolase; (3) cystathionine synthase; (4) cystathionase; (5) sulfite oxidase; (6) betaine homocysteine methyltransferase; (7) methionine synthase; (8) methylene tetrahydrofolate reductase.

severe hypertension (from renal infarcts) are among the serious consequences of thromboembolism, which is caused by changes in the vascular walls and by increased platelet adhesiveness secondary to elevated homocystine levels. The risk of thromboembolism increases after surgical procedures.

Elevations of both methionine and homocystine (or total homocysteine) in body fluids are the diagnostic *laboratory findings*. Freshly voided urine should be tested for homocystine, because this compound is unstable and may disappear as the urine is stored. Cystine is low or absent in plasma. The *diagnosis* may be established by assay of the enzyme in liver biopsy specimens, cultured fibroblasts, or phytohemagglutinin-stimulated lymphocytes.

Treatment with high doses of vitamin B_6 (200–1,000?mg/24?hr) causes dramatic improvement in patients who are responsive to this therapy. The degree of response to vitamin B_6 treatment may be different in different families. Some patients may not respond because of folate depletion; a patient should not be considered unresponsive to vitamin B_6 until folic acid (1–5?mg/24?hr) has been added to the treatment regimen. Restriction of methionine intake in conjunction with cysteine supplementation is recommended for patients who are unresponsive to vitamin B_6 . The need for dietary restriction and its extent is controversial in patients with vitamin B_6 responsive form. In some patients with this form of the condition, addition of betaine may obviate the need for any dietary restriction. Betaine (trimethylglycine, 6–9?g/24?hr for adults or 200 to 250?mg/kg/day in children) lowers homocysteine levels in body fluids by remethylating homocysteine to methionine (see Fig. 74–3). This treatment has produced clinical improvement (preventing vascular events) in patients who are unresponsive to vitamin B_6 therapy.

More than 100 pregnancies in women with the classic form of homocystinuria have been reported with favorable outcomes for both mothers and infants. The majority of infants were full term and normal. Postpartum thromboembolic events occurred in a few mothers. All but 1 of the 38 affected male patients have had normal offspring.

The *screening* of newborn infants for classic homocystinuria yields a prevalence of 1:200,000 to 1:350,000; most are vitamin B_6 unresponsive. Because almost 40% of patients identified after the newborn period are vitamin B_6 responsive, one must assume that these screening programs miss the majority of infants with

---

the vitamin B_6 responsive form. Newer screening methods (tandem mass spectrometry) may improve the detection process. The condition seems more common in New South Wales, Australia (1:60,000). Early treatment of patients identified by the screening process has produced favorable results. The mean IQ of 16 patients with the vitamin B_6 unresponsive form treated in early infancy is 94. Dislocation of the lens may be preventable.

Homocystinuria is inherited as an autosomal recessive trait. The gene for cystathionine ß synthase is located on the long arm of chromosome 21. *Prenatal diagnosis* is feasible by performing an enzyme assay of cultured amniotic cells or chorionic villi. Many disease-causing mutations (over 100) have been identified in different families. The majority of affected patients are compound heterozygotes for two different alleles. Heterozygous carriers are usually asymptomatic, however; thromboembolic events and coronary heart disease are more common than in the normal population.

HOMOCYSTINURIA DUE TO DEFECTS IN METHYLCOBALAMIN FORMATION.

Methylcobalamin is the cofactor for the enzyme methionine synthase, which catalyzes remethylation of homocysteine to methionine. There are at least five distinct defects in the intracellular metabolism of cobalamin that may interfere with the formation of methylcobalamin. To better understand the metabolism of cobalamin, see methylmalonic acidemia (see Chapter 74.6 and Figs. 74–3 and 74–5). The five defects are designated as *cbl*C, *cbl*D, *cbl*E (methionine synthase reductase), *cbl*G (methionine synthase), and *cbl*F. Patients with *cbl*C, *cbl*D, and *cbl*F defects have methylmalonic acidemia in addition to homocystinuria because formation of both adenosylcobalamin and methylcobalamin is impaired (see Chapter 74.6).

Patients with *cbl*E and *cbl*G defects are unable to form methylcobalamin and develop homocystinuria without methylmalonic acidemia (see Fig. 74–5); only a few patients with these two defects are known (12 patients with *cbl*E and 24 patients with *cbl*G).

The *clinical manifestations* are similar in patients with all of these defects. Vomiting, poor feeding, lethargy, hypotonia, and developmental delay may occur in the first few months of life. However, one patient with the *cbl*G defect was not symptomatic (except for mild developmental delay) until she was 21 yr old, when she developed difficulty in walking and numbness of the hands. *Laboratory findings* include megaloblastic anemia, homocystinuria, and hypomethioninemia. The presence of megaloblastic anemia differentiates these defects from homocystinuria due to methylenetetrahydrofolate reductase deficiency (see later). The presence of hypomethioninemia differentiates both of these from cystathionine ß synthase deficiency (see earlier).

Diagnosis is established by complementation studies performed in cultured fibroblasts. *Prenatal diagnosis* has been accomplished by studies in amniotic cell cultures. The genes for *cbl*E (MTRR) and *cbl*G (MTR) have been identified.

Treatment with vitamin B_{12} in the form of hydroxycobalamin (1–2?mg/24?hr) is used to correct the clinical and biochemical findings. Results vary among both diseases and sibships.

HOMOCYSTINURIA DUE TO DEFICIENCY OF METHYLENETETRAHYDROFOLATE REDUCTASE (MTHFR).

This enzyme reduces 5–10 methylenetetrahydrofolate to form 5-methyltetrahydrofolate, which provides the methyl group needed for remethylation of homocysteine to methionine (see Fig. 74–3).

The severity of the enzyme defect and of the *clinical manifestations* varies considerably in different families. Complete absence of enzyme activity results in neonatal apneic episodes and myoclonic seizures that may lead rapidly to coma and death. Partial deficiency may result in a more chronic clinical picture, manifested by mental retardation, convulsions, microcephaly, and spasticity. One 15-yr-old patient developed schizophrenia and mental deterioration at 11 yr of age. Premature vascular disease or peripheral neuropathy has been reported as the only manifestation of this enzyme deficiency in some patients. One affected adult was completely asymptomatic. A common polymorphism (677C(T) causes enzyme thermal lability, mildly elevated total plasma homocysteine levels, and lower levels of plasma folate. Homozygosity for this polymorphism has been implicated as a risk factor for both vascular disease and neural tube defects.

Laboratory findings include moderate homocystinemia and homocystinuria. The methionine concentration is low or low normal. This finding differentiates this condition from classic homocystinuria caused by cystathionine synthase deficiency. Absence of megaloblastic anemia distinguishes this condition from homocystinuria caused by defects in methylcobalamin formation (see earlier). Thromboembolism of vessels has also been observed in these patients. *Diagnosis* may be confirmed by the enzyme assay in cultured fibroblasts and leukocytes.

Treatment with a combination of folic acid, vitamin B_6 , vitamin B_{12} , methionine supplementation, and betaine has been tried. Early treatment with betaine seems to have the most beneficial effect.

The gene for this enzyme has been located on the short arm of chromosome 1. The condition is transmitted as an autosomal recessive trait; more than 40 cases have been reported.

Hypermethioninemia.

Secondary hypermethioninemia occurs in liver disease, tyrosinemia type I, and classic homocystinuria. Hypermethioninemia has also been found in premature and some full-term infants receiving high-protein diets, in whom it may represent delayed maturation of the enzyme methionine adenosyltransferase. Lowering the protein intake usually resolves the abnormality. *Primary hypermethioninemia* caused by the deficiency of hepatic methionine adenosyltransferase (see Fig. 74–3) has been reported in a few patients who have been diagnosed in the neonatal period through screening for homocystinuria. Affected individuals with residual enzyme activity remain asymptomatic throughout life despite persistent hypermethioninemia. Some complain of unusual odor to their breath (boiled cabbage). A few patients with complete enzyme deficiency have had neurologic abnormalities related to demyelination (mental retardation, dystonia, dyspraxia). The gene for methionine adenosyltransferase is located on the long arm of chromosome 10 and several disease-causing mutations have been identified. A novel defect, glycine *N*-methyltransferase deficiency, also causes isolated hypermethioninemia.

Cystathioninemia.

Secondary cystathioninuria occurs in patients with vitamin B_6 or B_{12} deficiency, liver disease (particularly with liver damage from galactosemia), thyrotoxicosis, hepatoblastoma, neuroblastoma, ganglioblastoma, or defects in remethylation of homocysteine.

Cystathionase deficiency results in massive cystathioninuria and mild to moderate cystathioninemia; cystathionine is not normally detectable in blood. Deficiency of this enzyme is inherited as an autosomal recessive trait. Affected subjects with a wide variety of clinical manifestations have been reported. Lack of a consistent clinical picture and the presence of cystathioninuria in a number of normal persons suggest that cystathionase deficiency may be of no clinical significance. A majority of reported cases are responsive to oral administration of large doses of vitamin B_6 (100?mg or more/24?hr). When cystathioninuria is discovered in a patient, vitamin B_6 treatment seems indicated, but its beneficial effect has not been established.

74.4 Cysteine/Cystine

Iraj Rezvani

Cysteine is a sulfur-containing nonessential amino acid that is synthesized from methionine (see Fig. 74–3). In the presence of oxygen, two molecules of cysteine are oxidized to form cystine.

The most common disorders of cysteine/cystine metabolism, cystinuria (see Chapter 539) and cystinosis (see Chapter 521.3), are discussed elsewhere.

Sulfite Oxidase Deficiency (Molybdenum Cofactor Deficiency).

At the last step in cysteine metabolism, sulfite is oxidized to sulfate by sulfite oxidase, and the sulfate is excreted in the urine (see Fig. 74–3). This enzyme requires a molybdenum-pterin complex named molybdenum cofactor. This cofactor is also necessary for the function of two other enzymes in humans, xanthine dehydrogenase (which oxidizes xanthine and hypoxanthine to uric acid) and aldehyde oxidase. Most patients who were originally diagnosed as having sulfite oxidase deficiency have been proven to have molybdenum cofactor deficiency. Both conditions are inherited as autosomal recessive traits.

Both the enzyme and the cofactor deficiencies produce identical *clinical manifestations*. Refusal to feed, vomiting, severe intractable seizures (tonic, clonic, and myoclonic), and severe developmental delay may develop within a few weeks after birth. Bilateral dislocation of ocular lenses is a common finding in patients who survive the neonatal period.

These children excrete large amounts of sulfite, thiosulfate, S-sulfocysteine, xanthine, and hypoxanthine in their urine. Urinary and serum levels of uric acid and urinary concentration of sulfate are diminished. Fresh urine should be used for screening purposes and for quantitative measurements of sulfite, because oxidation at room temperature may produce false-negative results.

Diagnosis is confirmed by measurement of sulfite oxidase and molybdenum cofactor in fibroblasts and liver biopsies, respectively. *Prenatal diagnosis* is possible by performing an assay of sulfite oxidase activity in cultured amniotic cells or in samples of chorionic villi.

No effective *treatment* is available, and most children die during the first 2 yr of life.

74.5 Tryptophan

Iraj Rezvani

Tryptophan is an essential amino acid and a precursor for nicotinic acid and serotonin (Fig. 74–4). Presumed deficiencies of a variety of enzymes involved in tryptophan catabolism have

Figure 74.5-4 Pathways in the metabolism of tryptophan. PKU* indicates hyperphenylalaninemia due to tetrahydrobiopterin deficiency (see Fig. 74–1). **Enzymes:** (1) tryptophan hydroxylase; (2) aromatic L-amino acid decarboxylase (AADC); (3) monoamine oxidase (MAO).

been reported but no distinct clinical entity has emerged. Hartnup disorder causes disturbance in tryptophan absorption.

Hartnup Disorder.

In this autosomal recessive disorder, there is a single defect in the transport of monoamino-monocarboxylic amino acids (neutral amino acids) by the intestinal mucosa and renal tubules. Most children with Hartnup defect remain asymptomatic. The major *clinical manifestation* in the rare symptomatic patient is cutaneous photosensitivity. The skin becomes rough and red after moderate exposure to the sun, and with greater exposure a pellagra-like rash may develop. The rash may be pruritic, and a chronic eczema may appear. The skin changes have been reported in affected infants as young as 10 days of age. Some patients may have intermittent ataxia manifested as an unsteady, wide-based gait. The ataxia may last a few days and usually recovers spontaneously. Mental development is usually normal. However, two individuals in the original kindred were mentally retarded. Episodic psychologic changes, such as irritability, emotional instability, depression and suicidal tendencies, have been observed; these changes are usually associated with bouts of ataxia. Short stature and atrophic glossitis are seen in some patients.

Almost all children who were diagnosed with Hartnup disorder as a result of neonatal screening have remained asymptomatic. This indicates that other factors are also involved in pathogenesis of the clinical condition.

The main *laboratory finding* is aminoaciduria, which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, and histidine). Urinary excretion of proline, hydroxyproline, and arginine remains normal. This important diagnostic finding differentiates Hartnup disorder from other causes of generalized aminoaciduria, such as Fanconi syndrome. Plasma concentrations of neutral amino acids are usually normal. This seemingly unexpected finding is because amino acids are also absorbed as dipeptides; this transport system is intact in Hartnup disorder. The indole derivatives (especially indican) may be found in large amounts in this disorder, owing to bacterial breakdown of unabsorbed tryptophan in the intestines.

Diagnosis is established by the striking intermittent nature of symptoms and the just described urinary findings.

Treatment with nicotinic acid or nicotinamide (50–300?mg/24?hr) and a high-protein diet has resulted in a favorable

---

response in symptomatic patients. Because of the intermittent nature of the clinical manifestations, the efficacy of these treatments is difficult to evaluate.

74.6 Valine, Leucine, Isoleucine, and Related Organic Acidemias

Iraj Rezvani
David S. Rosenblatt *

The early steps in the degradation of these three essential amino acids, the *branched-chain amino acids*, are similar (Fig. 74–5). The intermediate metabolites are all organic acids, and deficiency of any of the degradative enzymes, except for the transaminases, causes acidosis; in such instances, the organic acids before the enzymatic block accumulate in body fluids and are excreted in the urine. These disorders commonly cause severe metabolic acidosis, which usually occurs during the first few days of life. Although most of the clinical findings are nonspecific, some manifestations may provide important clues to the nature of the enzyme deficiency. An approach to infants suspected of having an organic acidemia is presented in Figure 74–6 . Definitive diagnosis is usually established by identifying and measuring specific organic acids in body fluids (blood, urine) and by the enzyme assay.

Organic acidemias are not limited to defects in the catabolic pathways of branched-chain amino acids. Disorders causing accumulation of other organic acids include those derived from lysine (see Chapter 74.13), those associated with lactic acid (see Chapter 76), and dicarboxylic acidemia associated with defective fatty acid degradation (see Chapter 75.1).

Maple Syrup Urine Disease (MSUD).

Decarboxylation of leucine, isoleucine, and valine is accomplished by a complex enzyme system (branched-chain a-ketoacid dehydrogenase) using thiamine pyrophosphate (vitamin B_1) as a coenzyme. This mitochondrial enzyme consists of four subunits: E_{1a} , $E_{1ß}$, E_2 , and E_3 . The E_3 subunit is shared with two other dehydrogenases in the body, namely, pyruvate dehydrogenase and a-ketoglutarate dehydrogenase. Deficiency of this enzyme system causes MSUD (see Fig. 74–5), named after the sweet odor of maple syrup found in body fluids, especially urine. Based on clinical findings and response to thiamine administration, five phenotypes of MSUD have been identified.

CLASSIC MSUD.

This form has the most severe *clinical manifestations*. Affected infants are initially normal at birth but develop poor feeding and vomiting during the 1st wk of life; lethargy and coma may ensue within a few days. Physical examination reveals hypertonicity and muscular rigidity with opisthotonos. Periods of hypertonicity may alternate with bouts of flaccidity. Neurologic findings are often mistaken for sepsis and meningitis. Convulsions occur in most infants, and hypoglycemia is common. However, in contrast to most hypoglycemic states, correction of the blood glucose concentration does not improve the clinical condition. Routine *laboratory findings* are usually unremarkable, except for metabolic acidosis, which is not consistently observed. Death usually occurs in untreated patients within the first few weeks or months of life.

Diagnosis is often suspected because of the peculiar odor of maple syrup found in urine, sweat, and cerumen (see Fig. 74–6). It is usually confirmed by amino acid analysis showing marked elevations in plasma levels of leucine, isoleucine, valine, and alloisoleucine (a stereoisomer of isoleucine not normally found in blood) and depression of alanine. Leucine levels are usually higher than those of the other three amino acids. Urine contains high levels of leucine, isoleucine, and valine and their respective ketoacids. These ketoacids may be detected qualitatively by adding a few drops of 2,4-dinitrophenylhydrazine reagent (0.1% in 0.1 N HCl) to the urine; a yellow precipitate of 2,4 dinitrophenylhydrazone is formed in a positive test. Neuroimaging during the acute state shows cerebral edema, which is most prominent in the cerebellum, dorsal brain stem, cerebral peduncle, and internal capsule. Following the acute state and with advancing age, hypomyelination and cerebral atrophy may develop.

Treatment of the acute state is aimed at rapid removal of the branched-chain amino acids and their metabolites from the tissues and body fluids. Because renal clearance of these compounds is poor, hydration alone may not produce a rapid improvement. Peritoneal dialysis or hemodialysis are the most effective modes of therapy in critically ill infants and should be instituted promptly; significant decreases in plasma levels of leucine, isoleucine, and valine are usually seen within 24?hr of treatment. Providing sufficient calories and nutrients intravenously or orally should reverse the patient's catabolic state.

Treatment after recovery from the acute state requires a low branched-chain amino acid diet with synthetic formulas devoid of leucine, isoleucine, and valine. Because these amino acids cannot be synthesized endogenously, small amounts of them should be added to the diet; the amount should be titrated carefully by performing frequent analyses of the plasma amino acids. A clinical condition resembling *acrodermatitis enteropathica* occurs in affected infants whose plasma isoleucine concentration becomes very low; addition of isoleucine to the diet causes a rapid and complete recovery. Patients with MSUD should remain on the diet for the rest of their lives. Liver transplantation has been performed in a small number of patients with classic MSUD with promising results. These children are able to tolerate a normal diet.

The long-term *prognosis* of affected children remains guarded. Severe ketoacidosis, cerebral edema, and death may occur during any stressful situation, such as infection or surgery, especially in mid childhood. Mental and neurologic deficits are common sequelae.

INTERMITTENT MSUD.

In this form, seemingly normal children develop vomiting, odor of maple syrup, ataxia, lethargy, and coma during any stress or catabolic state such as infection or surgery. During these attacks, laboratory findings are indistinguishable from those of

the classic form, and death may occur. *Treatment* of the acute attack of intermittent MSUD is similar to that of the classic form. After recovery, although a normal diet is tolerated, a diet low in branched-chain amino acids is recommended. Activity of dehydrogenase in patients with the intermittent form is higher than in the classic form and may reach 5–20% of the normal activity.

MILD (INTERMEDIATE) MSUD.

In this form, affected children develop milder disease after the neonatal period. *Clinical manifestations* are insidious and limited to the central nervous system. Patients have mild to moderate mental retardation (usually after 5 mo of age) with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the branched-chain amino acids and their ketoacid derivatives in the urine. Plasma concentrations of leucine, isoleucine, and valine are moderately increased whereas those of lactate and pyruvate are normal. These children are commonly diagnosed during an intercurrent illness when signs and symptoms of classic MSUD may occur. The dehydrogenase activity is 3–30% of normal. Since patients with thiamine-responsive MSUD usually have manifestations similar to those seen in the mild form, a trial of thiamine therapy is recommended. Diet therapy, similar to that of classic MSUD, is needed.

THIAMINE-RESPONSIVE MSUD.

Some children with mild or intermediate forms of MSUD who are treated with high doses of thiamine have dramatic clinical and biochemical improvement. Although some responded to treatment with 10?mg/24?hr

* David S. Rosenblatt contributed to the section on Methylmalonic Acidemia.

Figure 74.6-5 Pathways in the metabolism of the branched-chain amino acids, biotin, and vitamin B_{12} (cobalamin). MMA = methylmalonic acidemia; HCU = homocystinuria; Cbl = cobalamin; OHCbl = hydroxycobalamin; cbl = defect in metabolism of cobalamin; TC = transcobalamin.

thiamine, others may require as much as 200?mg/24?hr for at least 3 wk before a favorable response is observed. These patients also require diets deficient in branched-chain amino acids. The enzymatic activity in these patients is 2–40% of normal.

MSUD DUE TO A DEFICIENCY OF E3 SUBUNIT (DIHYDROLIPOYL DEHYDROGENASE).

This is a very rare disorder. Patients develop lactic acidosis in addition to signs and symptoms similar to those of intermediate MSUD because the E_3 subunit is also a component of pyruvate dehydrogenase and a-ketoglutarate dehydrogenase. Progressive neurologic impairment manifested by hypotonia and developmental delay occurs after 2 mo of age. Abnormal movements progress to ataxia. Death may occur in early childhood.

Laboratory findings include persistent lactic acidosis with high levels of plasma lactate, pyruvate, and alanine. Plasma concentrations of branched-chain amino acids are moderately increased. Patients excrete large amounts of lactate, pyruvate, a-glutarate, and the three branched-chain ketoacids in their urine.

Figure 74.6-6 Clinical approach to infants with organic acidemia. Asterisks indicate disorders in which patients have a characteristic odor (see text and Table 73–1).

No effective *treatment* is available. Dietary restriction of branched-chain amino acids and treatment with high doses of thiamine, biotin, and lipoic acid has been ineffective.

GENETICS AND PREVALENCE OF MSUD.

All forms of MSUD are inherited as an autosomal recessive trait. The enzyme activity can be measured in leukocytes and cultured fibroblasts. The gene for each subunit resides on different chromosomes. The $E_{1\beta}$ gene is on the long arm of chromosome 19; $E_{1\beta}$ is on the short arm of chromosome 6; E_2 is on the short arm of chromosome 1; and E_3 is on the long arm of chromosome 7. Many different disease-causing mutations have been identified in patients with different forms of MSUD. A given phenotype is caused by a variety of genotypes. Patients from different pedigrees with the classic form of MSUD have been shown to have mutations in genes for E_{1a}, $E_{1\beta}$, or E_2. Most patients are compound heterozygotes inheriting two different mutant alleles.

The *prevalence* is estimated at 1:185,000. The classic form of MSUD is quite prevalent in the Old Order of Mennonites in the United States and is estimated to be 1:176. Affected patients in this population are homozygous for a specific mutation (Try_{393} -to-Asn) in the E_{1a} subunit gene.

Successful methods for *mass screening* of newborn infants are being used in the United States and other countries. *Prenatal diagnosis* has been accomplished by enzyme assay of the cultured aminocytes, cultured chorionic villi tissue, or direct assay of the chorionic villi samples.

Several successful pregnancies have occurred in women with different forms of MSUD. No ill effects have been observed in the offspring of these patients. Episodes of metabolic decompensations have occurred in the mothers during pregnancy and the postpartum period.

Isovaleric Acidemia.

This rare condition is due to the deficiency of isovaleryl CoA dehydrogenase (see

Fig. 74–5).

Clinical manifestations in the *acute form* (about 50% of cases) include vomiting and severe acidosis in the first few days of life. Lethargy, convulsions, and coma may ensue, and death may occur if proper therapy is not initiated. The vomiting may be severe enough to suggest pyloric stenosis. The characteristic odor of “sweaty feet” may be present (see Fig. 74–6). Infants who survive this acute episode will go on to have the chronic intermittent form later on in life. A milder form of the disease *(chronic intermittent form)* also exists in which the first clinical manifestation (vomiting, lethargy, acidosis or coma) may not appear until the infant is a few months or a few years old. In both forms, acute episodes of metabolic decompensations may occur during a catabolic state such as an infection. Both forms of the disease have been observed in the same family.

Laboratory findings during the acute attacks include severe ketoacidosis, neutropenia, thrombocytopenia, and, occasionally, pancytopenia. Hypocalcemia, hyperglycemia, and moderate to severe hyperammonemia may be present in some patients. Increases in plasma ammonia may suggest a defect in the urea cycle. However, in the latter conditions the infant is not acidotic (see Fig. 74–6).

Diagnosis is established by demonstrating marked elevations of isovaleric acid and its metabolites (isovalerylglycine, 3-hydroxyisovaleric acid) in body fluids, especially urine. The main compound in plasma is isovalerylcarnitine, which can be measured even in a few drops of dried blood on a filter paper. Measuring the enzyme in cultured skin fibroblasts confirms the diagnosis.

Treatment of the acute attack is aimed at hydration, reversal of the catabolic state (by providing adequate calories orally or intravenously), correction of metabolic acidosis (by infusing sodium bicarbonate), and removal of the excess isovaleric acid. Because isovalerylglycine has a high urinary clearance, administration of glycine (250?mg/kg/24?hr) is recommended to enhance formation of isovalerylglycine. Carnitine (100?mg/kg/24?hr) also increases removal of isovaleric acid by forming isovalerylcarnitine, which is excreted in the urine. In patients with significant hyperammonemia (blood ammonia > 200?µM), measures that reduce blood ammonia should be employed (see Chapter 74.11). Exchange transfusion and peritoneal dialysis may be needed if the previously mentioned measures fail to induce significant clinical and biochemical improvement. After recovery from the acute attack, the patient should be kept on a low-protein diet (1.0–1.5?g/kg/24?hr) and should be given glycine and carnitine supplements. Pancreatitis (acute or recurrent forms) has been reported in survivors. Normal development can be achieved with early and proper treatment. *Prenatal diagnosis* has

been accomplished by measuring isovalerylglycine in amniotic fluid or by enzyme assay in cultured amniocytes. Successful *pregnancy* with favorable outcomes both for the mother and the infant has been reported. Successful methods for *mass screening* of newborn infants are being used in the United States and other countries. Isovaleric acidemia is inherited as an autosomal recessive trait. The gene has been mapped to the long arm of chromosome 15. The gene frequency in the general population is not known.

Multiple Carboxylase Deficiencies (Defects in Utilization of Biotin).

Biotin is a water-soluble vitamin that is a cofactor for all four carboxylase enzymes: pyruvate carboxylase, acetyl CoA carboxylase, propionyl CoA carboxylase, and 3-methylcrotonyl-CoA-carboxylase. The latter two are involved in the metabolic pathways of leucine, isoleucine, and valine (see Fig. 74–5).

Dietary biotin is bound to proteins; free biotin is generated in the intestine by the action of digestive enzymes, by intestinal bacteria and perhaps by biotinidase. The latter enzyme, which is found in serum and most tissues in the body, is also essential for the recycling of biotin in the body by releasing it from the apoenzymes (carboxylases, see Fig. 74–5). Free biotin must form a covalent peptide bond with the apoprotein of the previously mentioned carboxylases to activate them (holocarboxylase). This binding is catalyzed by holocarboxylase synthetase. Deficiencies in this enzyme or in biotinidase result in malfunction of all the carboxylases and in organic acidemia.

HOLOCARBOXYLASE SYNTHETASE DEFICIENCY (MULTIPLE CARBOXYLASE DEFICIENCY—INFANTILE OR EARLY FORM).

Infants with this rare autosomal recessive disorder become symptomatic in the first few weeks of life. Symptoms may appear as early as a few hours after birth to 21 mo of age. *Clinically*, the affected infants who seem normal at birth develop breathing difficulties (tachypnea and apnea) shortly after birth. Feeding problems, vomiting, and hypotonia are also commonly present. If the condition remains untreated, a generalized erythematous rash with exfoliation and alopecia (partial or total), failure to thrive, irritability, seizures, lethargy, and even coma may occur. Developmental delay is common. Immune deficiency manifests as susceptibility to infection. The urine may have a peculiar odor, which has been described as similar to tomcat urine. The rash, when present, differentiates this condition from other organic acidemias (see Fig. 74–6).

Laboratory findings include metabolic acidosis, ketosis, hyperammonemia, and the presence of a variety of organic acids, which include lactic acid, propionic acid, 3-methylcrotonic acid, 3-methylcrotonylglycine, methylcitrate, and 3-hydroxyisovaleric acid in body fluids. *Diagnosis* is confirmed by the enzyme assay in lymphocytes or cultured fibroblasts. The mutant enzyme usually has an increased K_m value for biotin. Enzyme activity may be restored by the administration of large doses of biotin.

Treatment with biotin (10?mg/day orally) usually results in an improvement in clinical manifestations and may normalize the biochemical abnormalities. Early diagnosis and treatment are critical to prevent irreversible neurologic damage. In some patients, however, complete resolution may not be achieved even with large doses (up to 80?mg/day) of biotin.

The gene for holocarboxylase synthetase is located on the long arm of chromosome 21, and multiple disease-causing mutations have been identified in different families. All reported cases are compound heterozygotes inheriting two different mutant

alleles. Prenatal diagnosis has been accomplished by assaying enzyme activity in cultured amniotic cells and by measurement of intermediate metabolites (3-hydroxyisovalerate and methylcitrate) in amniotic fluid. Two pregnant mothers who had previous offspring with holocarboxylase synthetase deficiency have been treated with biotin late in pregnancy (23 and 34 wk of gestation). Affected infants were normal at birth but the efficacy of the treatment and the outcome remain unclear.

BIOTINIDASE DEFICIENCY (MULTIPLE CARBOXYLASE DEFICIENCY-JUVENILE OR LATE FORM).

The absence of biotinidase results in biotin deficiency. The prevalence of this autosomal recessive trait is estimated at 1 in 60,000.

Infants with this deficiency may develop *clinical manifestations* similar to those seen in infants with holocarboxylase synthetase deficiency, but, unlike the latter, symptoms may appear later, when the child is several months or several years old; symptoms may develop as early as 1 wk of age. The term “late form” does not apply to all cases and can be misleading. The delay is presumably because of the presence of sufficient free biotin derived from the mother or the diet. Atopic or seborrheic dermatitis, alopecia, ataxia, myoclonic seizures, hypotonia, developmental delay, sensorineural hearing loss, and immunodeficiency (from T-cell abnormalities) may occur. Children with intractable seborrheic dermatitis may have partial (15–30% activity) deficiency of the enzyme; these children are otherwise asymptomatic, and their dermatitis was resolved with biotin therapy. Asymptomatic children and adults with this enzyme deficiency have been identified in screening programs. Most of these individuals have been shown to have partial deficiency of the enzyme activity.

Laboratory findings and the pattern of organic acids in body fluids resemble those associated with holocarboxylase synthetase deficiency (see earlier). *Diagnosis* can be established by measurement of the enzyme activity in the serum. A simplified method for mass screening of newborn infants is in use in several states in the United States and around the world.

Treatment with free biotin (5–20?mg/24?hr) results in a dramatic clinical and biochemical response. Treatment with biotin is also suggested for individuals with partial biotinidase deficiency.

The gene for biotinidase is located on the short arm of chromosome 3 and several disease-causing mutations have been identified in different families. *Prenatal diagnosis* is possible by the measurement of the enzyme activity in the amniotic cells or by identification of the mutant gene.

MULTIPLE CARBOXYLASE DEFICIENCY DUE TO DIETARY BIOTIN DEFICIENCY.

Acquired deficiency of biotin may occur in infants receiving total parenteral nutrition without added biotin, in patients receiving prolonged anticonvulsant drugs (phenytoin, primidone, carbamazepine), or in children with short gut syndrome or chronic diarrhea who are receiving formulas low in biotin. Excessive ingestion of raw eggs may also cause biotin deficiency because the protein avidin in egg white binds biotin and makes it unavailable for absorption. Infants with biotin deficiency develop dermatitis, alopecia, and candidal skin infections.

Isolated 3-Methylcrotonyl-CoA Carboxylase Deficiency.

This enzyme is one of the four carboxylase enzymes in the body that requires biotin as a cofactor (see Fig. 74–5). An isolated deficiency of this enzyme must be differentiated from disorders of biotin metabolism (multiple carboxylase deficiency), which cause diminished activity of all four carboxylases. 3-Methylerotonyl-CoA carboxylase is a heteromeric enzyme consisting of a (biotin-containing) and ß subunits. The gene for ß subunit *(MCCA)* is located on the long arm of chromosome 3q25-27 and that for the ß subunit *(MCCB)* is mapped to the long arm of chromosome 5q12-13. Mutation in either of these genes may result in the deficiency of the enzyme activity. Similar phenotype may be caused by different genotype. Several disease-causing mutations in either gene have been identified in different families.

Clinical manifestations are highly variable, ranging from fatal neonatal onset with acidosis, severe hypotonia and seizures, to asymptomatic adults. Typically, affected infants who have been seemingly normal develop an acute episode of vomiting, hypotonia, lethargy, and convulsions after a minor infection. Death may occur during the acute episode.

Laboratory findings during acute episodes include mild to moderate acidosis, ketosis, severe hypoglycemia, hyperammonemia, and elevated serum levels of liver transaminases. Large amounts of 3-hydroxyisovaleric acid and 3-methylcrotonylglycine are found in the urine. Urinary excretion of 3-methylcrotonic acid is not usually increased in this condition because the accumulated 3-methylcrotonyl CoA is converted to 3-hydroxyisovaleric acid. Severe secondary carnitine deficiency is common. The condition should be differentiated biochemically from multiple carboxylase deficiency (see earlier) in which lactic acid and metabolites of propionic acid are present in body fluids in addition to 3-hydroxyisovaleric acid. *Diagnosis* may be confirmed by measurement of the enzyme activity in cultured fibroblasts. Documentation of normal activities of other carboxylases is necessary for definitive diagnosis.

Aggressive *treatment* of acute episodes with hydration, intravenous infusion of glucose, and alkali is recommended. These patients are unresponsive to biotin therapy. Long-term treatment includes a diet restricted in leucine in conjunction with the oral administration of carnitine (75–100?mg/kg/24?hr) and the prevention of catabolic states. Normal growth and development are expected in these patients. The condition is inherited as an autosomal recessive trait.

Screening programs using tandem mass spectrometry have identified an unexpectedly high number of infants with 3-methylcrotonyl CoA carboxylase deficiencies, suggesting that this condition may be the most common organic acidemia.

3-Methylglutaconic Aciduria.

At least three inherited conditions are known to be associated with excessive excretion of 3-methylglutaconic acid in the urine. Deficiency of the enzyme 3-methylglutaconyl CoA hydratase (see Fig. 74–5) is present in type I. In the other two conditions the enzyme activity is normal despite a modest 3-methylglutaconic aciduria.

3-METHYLGLUTACONIC ACIDURIA TYPE I (3-METHYLGLUTACONYL COA HYDRATASE DEFICIENCY) (see Fig. 74–5).

This rare autosomal recessive condition is manifested by speech retardation, mild psychomotor delay, and the development of metabolic acidosis during a catabolic state. Patients excrete large amounts of 3-methylglutaconic acid and moderate amounts of 3-hydroxyisovaleric and 3-methylglutaric acids. Deficiency of 3-methyltaconyl CoA hydratase has been shown in cultured fibroblasts and lymphoblasts. *Treatment* with a low protein diet has been suggested. Beneficial effects of this therapy on the clinical course of the disease are doubtful. Administration of l-carnitine has resulted in clinical improvement in one patient.

3-METHYLGLUTACONIC ACIDURIA TYPE II (X-LINKED CARDIOMYOPATHY, NEUTROPENIA, GROWTH RETARDATION, AND 3-METHYLGLUTACONIC ACIDURIA WITH NORMAL 3-METHYLGLUTACONYL COA HYDRATASE, BARTH SYNDROME).

Over 30 male patients with this condition have been reported. *Clinical manifestations*, which usually occur shortly after birth, include dilated cardiomyopathy (manifested as respiratory distress and heart failure), hypotonia, growth retardation, and moderate to severe neutropenia. Mild lactic aciduria and/or hypoglycemia are seen in some patients. If patients survive infancy, relative improvement may occur with advancing age. Cognitive development is usually normal despite delayed motor function.

Laboratory findings include mild to moderate increases in urinary excretion of 3-methylglutaconic, 3-methylglutaric, and 2-ethylhydracrylic acids. Neutropenia is a common finding. Lactic acidosis, hypoglycemia, and abnormal mitochondrial ultrastructure are noted in some patients. Unlike 3-methylglutaconic aciduria type I, urinary excretion of 3-hydroxyisovaleric acid is not elevated.

The condition is inherited as an X-linked recessive trait. The gene has been mapped to the long arm of chromosome X. The activity of the enzyme 3-methylglutaconyl CoA hydratase is normal. The reason for the increased excretion of the above organic acids is not yet understood. No effective *treatment* is available.

3-METHYLGLUTACONIC ACIDURIA TYPE III (COSTEFF OPTIC ATROPHY SYNDROME).

Clinical manifestations in these patients include early-onset optic atrophy and later development of choreoathetoid movements, spasticity, ataxia, dysarthria, and mild developmental delay. All reported patients except one were Iraqi Jews living in Israel. These patients excrete moderate amounts of 3-methylglutaconic and 3-methylglutaric acids. The reason for the increased excretion of these organic acids has not been elucidated. Activity of the enzyme 3-methylglutaconyl CoA hydratase has been normal. The condition is inherited as an autosomal recessive trait. The gene for this condition *(OPA3)* is mapped to the long arm of chromosome 19q13.2-13.3. No effective *treatment* is available.

ß-Ketothiolase Deficiency (Mitochondrial Acetoacetyl-CoA Thiolase Deficiency).

This reversible mitochondrial enzyme cleaves 2-methylacetoacetyl CoA (see Fig. 74–5) or acetoacetyl CoA in one direction and synthesizes these compounds in a reverse action (Fig. 74–7).

Clinical manifestations are quite variable, ranging from an asymptomatic course in an adult to severe episodes of acidosis starting in the 1st yr of life. These children have intermittent episodes of unexplained ketosis and acidosis. These episodes usually occur after an intercurrent infection and respond quickly to intravenous fluids and bicarbonate therapy. Mild to moderate hyperammonemia may also be present during attacks. Both hypoglycemia and hyperglycemia have been reported in isolated cases. The child may be completely asymptomatic between episodes and may tolerate a normal protein diet well. Mental development is normal in most children. The episodes may be misdiagnosed as salicylate poisoning because of the similarity of clinical findings and the interference of elevated blood levels of acetoacetate with the colorimetric assay for salicylate.

Laboratory findings during the acute attack include acidosis, ketosis, and hyperammonemia. The urine contains large amounts of 2-methylacetoacetate and its decarboxylation product, butanone, 2-methyl-3-hydroxybutyrate. Lower concentrations of these urinary metabolites persist during the seemingly well periods. Mild hyperglycinemia may also be present. The clinical and biochemical findings should be differentiated from those seen with propionic and methylmalonic acidemias (see later). *Diagnosis* may be established by assay of the enzyme in cultured fibroblasts.

Treatment of acute episodes includes hydration and infusion of bicarbonate to correct the acidosis; a 10% glucose solution with the appropriate electrolytes and intravenous lipids may be used to minimize the catabolic state. Restriction of protein intake (1–2?g/kg/24?hr) is recommended for long-term therapy. Oral l-carnitine (50–100?mg/kg/24?hr) is also recommended to prevent possible secondary carnitine deficiency. Long-term *prognosis* for achieving normal life seems very favorable. Three patients graduated from high school and one has attended college. All patients continued to have abnormal metabolites in body fluids. Successful pregnancy with normal outcomes for both mother and infant has been reported.

The pathogenesis of ketosis in this condition is not adequately explained because, in this enzyme deficiency, one expects impaired ketone formation (see Fig. 74–7). It is postulated that excess acetoacetyl CoA produced from other sources is used as a substrate for 3-HMG-CoA synthesis in the liver.

This condition is inherited as an autosomal recessive trait and may be more prevalent than has been appreciated. The gene for this enzyme (T_2) is located on the long arm of chromosome 11q22.3-23.1.

Figure 74.6-7 Formation (liver) and metabolism (peripheral tissues) of ketone bodies and cholesterol synthesis. **Enzymes:** (1) mitochondrial acetoacetyl-CoA thiolase; (2) HMG-CoA synthase; (3) HMG-CoA lyase; (4) cytosolic acetoacetyl-CoA-thiolase; (5) mevalonic kinase; (6) succinyl-CoA; 3-ketoacid CoA transferase (SCOT).

Cystosolic Acetoacetyl CoA Thiolase Deficiency.

This enzyme catalyzes the cytosolic production of acetoacetyl CoA from 2 moles of acetyl CoA (see Fig. 74–7). Cytosolic acetoacetyl CoA is the precursor of hepatic cholesterol synthesis. Cytosolic acetoacetyl CoA thiolase is a completely different enzyme from that of mitochondrial thiolase (see earlier and Fig. 74–5). *Clinical manifestations* in patients with this rare enzyme deficiency are similar to those in patients with mevalonic acidemia (see later). Severe progressive developmental delay, hypotonia, and choreoathetoid movements develop in the first few months of life. *Laboratory findings* are nonspecific; elevated levels of lactate, pyruvate, acetoacetate, and 3-hydroxybutyrate may be found in blood and urine. One patient had normal levels of acetoacetate and 3-hydroxybutyrate. *Diagnosis* can be established by demonstrating a deficiency in cytosolic thiolase activity in liver biopsy or in cultured fibroblasts. No effective *treatment* is available. The gene for this condition is mapped to the long arm of chromosome 6q25.3-q26.

Mitochondrial 3-Hydroxy 3-Methylglutaryl-CoA (3-HMG-CoA) Synthase Deficiency.

This enzyme catalyzes synthesis of 3-HMG-CoA from acetoacetyl CoA in the mitochondria. This is a critical step in ketone body synthesis in the liver (see Fig. 74–7). Only two unrelated patients with deficiency of this enzyme have been reported. Hypoketotic hypoglycemic episodes occurred in one patient at age 18 mo and in the other at age 6 yr. Both children were asymptomatic before the episode and are normal afterward except for mild hepatomegaly with fatty infiltration. Laboratory findings were nonspecific; increases in medium-chain and short-chain dicarboxylic acids are found in the urine.

Treatment consisted of provision of adequate calories and avoidance of prolonged periods of fasting. No dietary protein restriction is needed.

The condition is presumably inherited as an autosomal recessive trait. The gene for this condition is located on the short arm of chromosome 1, and different mutations have been identified in the two families. The condition should be considered in any child with fasting hypoglycemia and is perhaps more common than appreciated.

3-Hydroxy-3-Methylglutaric Aciduria.

This condition is due to a deficiency of 3-hydroxy-3-methylglutaryl (3-HMG) CoA lyase (see Fig. 74–5). This enzyme catalyzes the conversion of 3-HMG CoA to acetoacetate and is a rate-limiting enzyme for ketogenesis (see Fig. 74–7). *Clinically*, over 60% of patients become symptomatic between 3 and 11 mo of age, whereas about 30% develop symptoms in the first few days of life. One child remained asymptomatic until 15 yr of age. Episodes of vomiting, severe hypoglycemia, hypotonia, acidosis with mild or no ketosis, and dehydration may rapidly lead to lethargy, ataxia, and coma. These episodes often occur during a catabolic state such as fasting or an intercurrent infection. Hepatomegaly is common.

These manifestations may be mistaken for Reye syndrome or medium-chain acyl CoA dehydrogenase (MCAD) deficiency. Patients are usually clinically asymptomatic between the attacks; one patient died of cardiomyopathy at age 7 mo. Development is usually normal, but mental retardation and seizure with MRI abnormalities of white matter have been observed in patients with prolonged episodes of hypoglycemia.

Laboratory findings include hypoglycemia, moderate to severe hyperammonemia, and acidosis. There is mild or no ketosis (see Fig. 74–7 for the explanation). Urinary excretion of 3-hydroxy-3-methylglutaric acid and other proximal intermediate metabolites of leucine catabolism (3-methylglutaconic acid and 3-hydroxyisovaleric acid) are markedly increased. These organic acids are excreted in the urine as carnitine conjugates resulting in secondary carnitine deficiency. Glutaric and adipic acids may also be increased in urine during acute attacks. *Diagnosis* may be confirmed by enzyme assay in cultured fibroblasts, leukocytes, or liver specimens. *Prenatal diagnosis* is possible with an assay of the enzyme in cultured amniocytes or in a chorionic villi biopsy.

Treatment of acute episodes includes hydration, infusion of glucose to control hypoglycemia, provision of adequate calories, and administration of bicarbonate to correct acidosis. Hyperammonemia should be treated promptly (see Chapter 74.11). Exchange transfusion and peritoneal dialysis may be required in patients with severe hyperammonemia. Restriction of protein and fat intake is recommended for long-term management. Oral administration of L-carnitine (50–100?mg/kg/24?hr, orally) prevents secondary carnitine deficiency. Prolonged fasting should be avoided. One child died after routine immunization. The condition is inherited as an autosomal recessive trait. The gene for 3-HMG-CoA lyase resides on the short arm of chromosome 1 and several disease-causing mutations have been identified in different families. The gene defect appears to be more common in the Arabic population, especially in Saudi Arabia.

Succinyl CoA: 3-Ketoacid CoA Transferase (SCOT) Deficiency.

This enzyme is necessary for the metabolism of ketone bodies (acetoacetate and 3-hydroxybutyrate) in peripheral tissue (see Fig. 74–7). A deficiency of this enzyme results in the underutilization and accumulation of ketone bodies and ketoacidosis. Only a few patients with SCOT deficiency have been reported; the condition may not be rare because many cases are undiagnosed.

The presentation is an acute episode of unexplained severe ketoacidosis in an infant who had been growing and developing normally. About half of the patients present in the 1st wk of life and in all before 2 yr. The acute episode is often precipitated by an intercurrent infection or a catabolic state. Death may occur during these episodes. A

chronic subclinical ketosis usually persists between the attacks. Development is usually normal.

Laboratory findings during the acute episode are nonspecific and include metabolic acidosis and ketonuria with high levels of acetoacetate and 3-hydroxybutyrate in blood and urine. No other organic acids are found in the blood or urine. Blood glucose levels are usually normal, but hypoglycemia has been reported in two newborn infants with severe ketoacidosis. Plasma amino acids are usually normal. *Diagnosis* can be established by demonstrating a deficiency of enzyme activity in cultured fibroblasts.

Treatment of acute episodes consists of hydration, correction of acidosis, and the provision of a diet adequate in calories. Long-term treatment with a high carbohydrate diet and avoidance of catabolic states is recommended. *This condition should be considered in any infant with unexplained bouts of ketoacidosis*. The condition is inherited as an autosomal recessive trait. The gene for this enzyme is located on the short arm of chromosome 5, and a limited number of disease-causing mutations have been found in different families.

Mevalonic Aciduria.

Mevalonic acid, an intermediate metabolite of cholesterol synthesis, is converted to 5-phosphomevalonic acid by the action of the enzyme mevalonate kinase (see Fig. 74–7). Based on the severity of clinical manifestations, two forms of this condition have been recognized.

MEVALONIC ACIDURIA, SEVERE FORM.

Clinical manifestations include mental retardation, failure to thrive, growth retardation, hypotonia, ataxia, hepatosplenomegaly, cataracts, and facial dysmorphism (dolichocephaly, frontal bossing, low-set ears, downward slanting of the eyes, and long eyelashes). Recurrent crises, characterized by fever, vomiting, diarrhea, arthralgia, edema, and morbilliform rash have been observed in all patients. These episodes last 4–5 days and recur up to 25 times per year. Death may occur during these crises.

Laboratory findings include marked elevation of mevalonic acid in urine; the concentration may be as high as 56,000?µmol/mol of creatinine (normal <0.3). Plasma levels of mevalonic acid are also greatly increased (as high as 54?µmol/dL; normal <0.004). This is the only abnormal organic acid found in these patients. The level of mevalonic acid tends to correlate with the severity of the condition and increases during crises. Serum cholesterol concentration is normal or mildly decreased. Serum concentration of creatine kinase (CK) is markedly increased. Sedimentation rate and serum leukotriene-4 are increased during the crises. Serial examination of the brain by MRI reveals progressive atrophy of the cerebellum.

Diagnosis may be confirmed by assay of mevalonate kinase activity in lymphocytes or in cultured fibroblasts. No effective therapy is available. *Treatment* with high doses of prednisone (2?mg/kg/24?hr) causes improvement of the acute crises. The condition is inherited as an autosomal recessive trait. *Prenatal diagnosis* is possible by measurement of mevalonic acid in the amniotic fluid or by assay of the enzyme activity in cultured amniocytes or chorionic villi samples. The gene for mevalonate kinase (MVK) is on the long arm of chromosome 12.

PERIODIC FEVER WITH HYPERGAMMAGLOBULINEMIA D, MEVALONIC ACIDURIA MILD FORM.

Periodic fever with hypergammaglobulinemia D is characterized by periodic bouts of fever associated with abdominal pain, arthralgia, arthritis, lymphadenopathy, and rash. The episodes, which may start in early infancy, occur every 1–2 mo and usually last 2–7 days. Mild to moderate mevalonic aciduria is present during the acute attack and normalizes during the well periods. The serum level of IgD is increased in most patients. The condition is inherited as an autosomal recessive trait with mutations in the gene for mevalonic aciduria *(MVK)*. Although, mutations in most families are different from those with severe forms of mevalonic aciduria, identical mutations have been reported in both types. The discrepancy between genotype and phenotype remains unexplained.

Propionic Acidemia (Propionyl CoA Carboxylase Deficiency).

Propionic acid is an intermediate metabolite of isoleucine, valine, threonine, methionine, odd-chain fatty acids, and cholesterol catabolism. It is normally carboxylated to methylmalonic acid by the mitochondrial enzyme propionyl CoA carboxylase, which requires biotin as a cofactor (see Fig. 74–5). The enzyme is composed of two nonidentical subunits, a and ß. Biotin is bound to the a subunit.

Clinical findings are nonspecific. The majority of patients develop symptoms in the first few days or weeks of life. Poor feeding, vomiting, hypotonia, lethargy, dehydration, and clinical signs of severe ketoacidosis progress rapidly to coma and death. Seizures occur in about 30% of affected infants. If an infant survives the first attack, similar episodes may occur during an intercurrent infection or constipation or after ingestion of a high-protein diet. Moderate to severe mental retardation and neurologic abnormalities such as dystonia, choreoathetosis, tremor, and pyramidal signs are common sequelae in the older

survivors. Less frequently, the older infant may have mental retardation without acute attacks of ketosis. Some affected children may have episodes of unexplained severe ketoacidosis separated by periods of seemingly normal health. The severity of clinical manifestations may also be variable within a family; in one kindred, a brother was diagnosed at 5 yr of age whereas his 13-yr-old sister, with the same level of enzyme deficiency, was asymptomatic. The reason for this wide variation in the phenotype remains unclear.

Laboratory findings during the acute attack include severe metabolic acidosis with a large anion gap, ketosis, neutropenia, thrombocytopenia, and hypoglycemia. Moderate to severe hyperammonemia is common, and plasma ammonia concentrations usually correlate with the severity. Measurement of plasma ammonia is especially helpful in planning therapeutic strategy during episodes of exacerbation in a patient whose diagnosis has been established. Hyperammonemia is believed to

be caused by inhibition of carbamoyl phosphate synthetase (CPS I) by the organic acid. Hyperglycinemia is common in patients with propionic acidemia. Elevations in plasma and urinary levels of glycine have also been observed in patients with methylmalonic acidemia. These disorders were collectively referred to as **ketotic hyperglycinemia** before the specific enzyme deficiencies were elucidated. Concentrations of propionic acid and methylcitric acid (presumably made by the condensation of propionyl CoA with oxaloacetic acid) are markedly elevated in the plasma and urine of infants with propionic acidemia. 3-Hydroxypropionic acid, propionylglycine, and other intermediate metabolites of isoleucine catabolism, such as tiglic acid, tiglyglycine, and 2-methyloacetoacetic acid, are also found in urine. Moderate elevations in blood levels of ammonia, glycine, and the previously mentioned organic acids are usually present between the acute attacks. CT and MRI of the brain may reveal evidence of cerebral atrophy, demyelination, and abnormalities in globus pallidus and basal ganglia. These findings represent infarctions caused by a cerebrovascular accident, which may occur during acute episode of metabolic decompensations. This complication (metabolic stroke) also may occur in patients with other organic acidemias and is a major cause of neurologic sequelae.

The *diagnosis* of propionic acidemia should be differentiated from multiple carboxylase deficiencies (see earlier description and Fig. 74–6). The latter infants may have skin manifestations and excrete large amounts of lactic acid, 3-methylcrotonic acid, and 3-hydroxyisovaleric acid in addition to propionic acid. The presence of hyperammonemia may suggest a genetic defect in the urea cycle enzymes. Infants with defects in the urea cycle are usually not acidotic (see Fig. 73–1). Definitive diagnosis of propionic acidemia can be established by measuring the enzyme activity in leukocytes or cultured fibroblasts.

Treatment of acute attacks includes hydration, correction of acidosis, and prevention of the catabolic state by provision of adequate calories through parenteral hyperalimentation. Minimal amounts of protein (0.25?g/kg/24?hr), preferably a protein deficient in propionate precursors, should be provided in the hyperalimentation fluid very early in the course of treatment. To curtail the possible production of propionic acid by intestinal bacteria, sterilization of the intestinal tract flora by antibiotics (oral neomycin or metronidazole) should be promptly initiated. Constipation should also be treated. Patients with propionic acidemia may develop carnitine deficiency, presumably as a result of urinary loss of propionylcarnitine formed from the accumulated organic acid. Administration of l-carnitine (50–100?mg/kg/24?hr orally or 10?mg/kg/24h intravenously) normalizes fatty acid oxidation and improves acidosis. In patients with concomitant hyperammonemia, measures to reduce blood ammonia should be employed (see Chapter 74.11). Very ill patients with severe acidosis and hyperammonemia require peritoneal dialysis or hemodialysis to remove ammonia and other toxic compounds. Although infants with true propionic acidemia are rarely responsive to biotin, this compound should be administered (10?mg/24?hr orally) to all infants during the first attack and until the diagnosis is established.

Long-term treatment consists of a low-protein diet (1.0–1.5?g/kg/24?hr) and administration of l-carnitine (50–100?mg/kg/24?hr orally). Synthetic proteins deficient in propionate precursors (isoleucine, valine, methionine, and threonine) may be used to increase the amount of dietary protein (to 1.5–2.0?g/kg/24?hr) while causing minimal change in propionate production. However, excessive supplementation with these proteins may cause a deficiency of the essential amino acids. To avoid this problem, natural proteins should comprise most of the dietary protein (50–75%). Some patients require chronic alkaline therapy to correct chronic acidosis. The concentration of ammonia in the blood usually normalizes between attacks, and chronic treatment of hyperammonemia is not usually needed. Catabolic states that may trigger acute attacks (e.g., infections and constipation) should be treated promptly and aggressively. Close monitoring of blood pH, amino acids, urinary content of propionate and its metabolites, and growth parameters is necessary to ensure the proper balance of the diet and the success of therapy.

Long-term *prognosis* is guarded. Death may occur during an acute attack. Normal psychomotor development is possible, but most children manifest some degree of permanent neurodevelopmental deficit such as dystonia, chorea, and pyramidal signs despite adequate therapy. These neurologic findings may be sequelae of a metabolic stroke occurring during an acute decompensation.

Prenatal diagnosis has been accomplished by measuring the enzyme activity in cultured amniotic cells and in samples of uncultured chorionic villi and by measurement of methylcitrate in amniotic fluid. Identification of the mutant gene in the family and in the fetus should provide a more precise method for prenatal DNA diagnosis.

The prevalence of propionic acidemia, inherited as an autosomal recessive trait, is not known. The gene for the a subunit (PCCA gene) is located on chromosome 13 and that of the ß subunit (PCCB gene) is mapped to the long arm of chromosome 3. Mutations in either gene have been identified in different patients.

Methylmalonic Acidemia.

Methylmalonic acid, a structural isomer of succinic acid, is normally derived from propionic acid as part of the catabolic pathways of isoleucine, valine, threonine, methionine, cholesterol, and odd-chain fatty acids. Two enzymes are involved in the conversion of d-methylmalonic acid to succinic acid, methylmalonyl CoA racemase (which forms the l-isomer) and methylmalonyl CoA mutase (which converts the l-methylmalonic acid to succinic acid) (see Fig. 74–5). The latter enzyme requires adenosylcobalamin, a metabolite of vitamin B_{12} , as a coenzyme. Deficiency of either the mutase or its coenzyme causes the accumulation of methylmalonic acid and its precursors in body fluids. A deficiency of the racemase has not been confirmed.

At least two forms of mutase apoenzyme deficiencies have been identified. These are designated mut^0 , meaning no detectable enzyme activity, and mut^- , indicating residual, although abnormal, mutase activity. The majority of reported patients with methylmalonic acidemia have a deficiency of the mutase apoenzyme (mut^0 or mut^-). These patients are not responsive to vitamin B_{12} therapy. In the remaining patients with methylmalonic acidemia the defect resides in the formation of adenosylcobalamin.

DEFECTS IN METABOLISM OF VITAMIN B_{12} (COBALAMIN).

Dietary vitamin B_{12} requires intrinsic factor, a glycoprotein secreted by the gastric

parietal cells, for absorption in the terminal ileum. It is transported in the blood by haptocorrin

(TCI) and transcobalamin II (TCII). The complex of transcobalamin II-cobalamin (TCII-Cbl) is recognized by a specific receptor on the cell membrane and enters the cell by endocytosis. The TCII-Cbl complex is hydrolyzed in the lysosome, and free cobalamin is released into the cytosol (see Fig. 74–5). The cobalt of the molecule is reduced in the cytosol from three valences (cob[III]alamin) to two (cob[II]alamin) before it enters the mitochondria, where further reduction to cob(I)alamin occurs. The latter compound reacts with adenosine to form adenosylcobalamin (coenzyme for methylmalonyl CoA mutase). The free cobalamin in the cytosol may also undergo a series of poorly understood enzymatic steps to form methylcobalamin (coenzyme for methionine synthase; see Fig. 74–3).

At least eight different defects in the intracellular metabolism of cobalamin have been identified. These are designated *cbl* A through H (*cbl* stands for a defect in any step of cobalamin metabolism). *cbl*A, *cbl*H, and *cbl*B cause methylmalonic acidemia only; *cbl*B is caused by a deficiency of adenosylcobalamin transferase. In patients with *cbl*C, *cbl*D, and *cbl*F defects, synthesis of both adenosylcobalamin and methylcobalamin is impaired, causing homocystinuria in addition to methylmalonic acidemia. The *cbl*E defect and the *cbl*G defect involve only the synthesis of methylcobalamin, resulting in homocystinuria without methylmalonic aciduria but usually with megaloblastic anemia.

Clinical manifestations of patients with methylmalonic acidemia due to mut^0 , mut^-, *cbl*A, *cbl*B, and *cbl*H are similar. There are wide variations in clinical presentation, ranging from very sick newborn infants to asymptomatic adults, regardless of the nature of the enzymatic defect or the biochemical abnormalities. Lethargy, feeding problems, vomiting, tachypnea (due to acidosis), and hypotonia may develop in the first few days of life and may progress to coma and death if untreated. Infants who survive the first attack may go on to develop similar acute metabolic episodes during a catabolic state (such as infection) or after ingestion of a high-protein diet. Between the acute attacks, the patient commonly continues to exhibit hypotonia and feeding problems with failure to thrive. In some patients the condition may present later in life with hypotonia, failure to thrive, and developmental delay. Asymptomatic patients with typical biochemical abnormalities of methylmalonic acidemia have been reported. The reason for this wide variation in clinical presentation remains unclear. It is important to note that mental development and IQ of patients with methylmalonic acidemia remain within the normal range despite repeated acute attacks and regardless of the nature of the enzyme deficiency. In one series with different forms of the condition developmental retardation was noted only in 47%. One adolescent girl with a mut^- deficiency has an IQ of 129.

The episodic nature of the condition and its biochemical abnormalities may be confused with those of ethylene glycol (antifreeze) ingestion. The peak of propionic acid in the assay has been mistaken as that of ethylene glycol.

Laboratory findings include ketosis, acidosis, anemia, neutropenia, thrombocytopenia, hyperglycinemia, hyperammonemia, hypoglycemia, and the presence of large quantities of methylmalonic acid in body fluids (see Fig. 74–6). Propionic acid and its metabolites 3-hydroxypropionate and methylcitrate are also found in the urine. Hyperammonemia may suggest defects in the urea cycle enzymes. Patients with defects in urea cycle enzymes are not acidotic (see Figs. 73–1 and 74–13). The increase in ammonia in patients with methylmalonic acidemia is believed to be caused by inhibition of carbamyl phosphate synthetase I (CPSI) enzyme by the organic acid.

Diagnosis can be confirmed by measuring propionate incorporation or mutase activity and by performing complementation studies in cultured fibroblasts.

Treatment of acute attacks is similar to that of attacks in patients with propionic acidemia (see earlier), except that large doses (1?mg/24?hr) of vitamin B_{12} are used instead of biotin. Long-term treatment consists of a low-protein diet (1.0–1.5?g/kg/24?hr) and administration of L-carnitine (50–100?mg/kg/24?hr) and vitamin B_{12} (1?mg/24?hr for patients with defects in vitamin B_{12} metabolism; the dose can be decreased depending on the clinical response). The protein composition of the diet is similar to that prescribed for patients with propionic acidemia. Chronic alkaline therapy is usually required to correct chronic acidosis, especially during infancy and early childhood. Blood levels of ammonia usually normalize between the attacks, and chronic treatment of hyperammonemia is rarely needed. Constipation and stressful situations that may trigger acute attacks (such as infection) should be prevented or treated promptly.

Inadequate oral intake secondary to poor appetite is a common and bothersome complication in long-term management of these patients. Consequently, enteral feeding (through a nasogastric tube or gastrostomy) should be considered early in the course of the treatment. Close monitoring of blood pH, amino acid levels, blood and urinary concentrations of methylmalonate, and growth parameters is necessary to ensure proper balance in the diet and the success of therapy. Glutathione deficiency, responsive to high doses of ascorbate, has been described in one patient. Liver and combined liver and kidney transplantations have been attempted with variable success.

Prognosis depends on the severity of symptoms and the occurrence of complications (see later). In general, patients with mutase apoenzyme deficiency (mut^0 , mut^-) have a less favorable prognosis and those with *cbl*A defect have a better outcome than those with *cbl*B.

The main *complication* is chronic renal failure necessitating renal transplant, which has been reported in a number of older patients with the condition and has been observed in all genetic forms of the condition. Tubulointerstitial nephritis has been documented in some of these patients and is thought to be the major cause of renal failure. The pathogenesis remains unclear.

Infarcts of the brain, especially those of the basal ganglia (globus pallidus) and internal capsule, have been reported in a few patients during an acute episode of metabolic decompensation (“metabolic stroke”). These patients have survived with major extrapyramidal (tremor, dystonia) and pyramidal (paraplegia) sequelae. The

pathogenesis of this complication also remains unclear.

Acute and recurrent pancreatitis has been reported in the affected patients as young as 13 mo of age. This complication may account for repeated hospitalizations of these children.

The *prevalence* of the condition is estimated at 1:48,000. Diagnosis has been accomplished by the assay of propionate incorporation in cultured amniotic cells. All defects causing methylmalonic acidemia are inherited as autosomal recessive traits. The gene for the mutase has been mapped to the short arm of chromosome 6, and at least 49 different mutations have been identified, including three common mutation (G717V, E117X, and N219Y). The genes for *cbl*A and *cbl*B defects have been cloned, but the gene for the *cbl*H defect has not yet been identified. Neonates with methylmalonic acidemia and severe diabetes caused by the absence of ß cells have been reported and have paternal uniparental isodisomy of chromosome 6.

Successful *pregnancy* with normal outcomes for both the mother and the baby has been reported.

Combined Methylmalonic Aciduria and Homocystinuria (*cbl*C, *cbl*D, and *cbl*F Defects).

Almost 200 patients with methylmalonic acidemia and homocystinuria due to *cbl*C, *cbl*D, and *cbl*F defects (see Figs. 74–3 and 74–5) are reported. The majority has the *cbl*C defect; only two brothers with *cbl*D and six patients with *cbl*F defects have been identified.

Neurologic findings are prominent in patients with *cbl*C and *cbl*D defects. Most patients with the *cbl*C defect present in the first few months of life because of failure to thrive, lethargy,

poor feeding, mental retardation, and seizures. However, late-onset defects with sudden development of dementia and myelopathy have been reported. Megaloblastic anemia is a common finding in patients with *cbl*C defect. Mild to moderate increases in concentrations of methylmalonic acid and homocysteine are found in body fluids. However, unlike patients with classic homocystinuria, plasma levels of methionine are low to normal in these defects. Neither hyperammonemia nor hyperglycinemia is observed in these patients. The first two patients with *cbl*F defect were females in whom poor feeding, growth and developmental delay, and persistent stomatitis became manifest in the first 3 wk of life. The first patient did not have megaloblastic anemia and homocystinuria, but both these signs were present in the second infant. Moderate methylmalonic acidemia was present in both infants. One patient was not diagnosed until age 10 yr and had findings suggestive of rheumatoid arthritis, a pigmented skin abnormality, and encephalopathy. Vitamin B_{12} malabsorption is noted in patients with *cbl*F defect.

Experience with *treatment* of patients with *cbl*C, *cbl*D, and *cbl*F defects is limited. Large doses of hydroxycobalamin (1–2?mg/24?hr) in conjunction with betaine (6–9?g/24?hr) produce biochemical improvement with little clinical effect. Unexplained severe hemolytic anemia, hydrocephalus, and congestive heart failure are major complications in patients with *cbl*C defect.

Patients with *cbl*E and *cbl*G defects do not have methylmalonic acidemia (see Chapter 74.3).

74.7 Glycine

Iraj Rezvani

Glycine is a nonessential amino acid synthesized mainly from serine and threonine. The main catabolic pathway requires the complex glycine cleavage enzyme to cleave the first carbon of glycine and convert it to carbon dioxide. The glycine cleavage protein, a mitochondrial multienzyme, is composed of four proteins: P protein, H protein, T protein, and L protein.

Hyperglycinemia.

Elevated levels of glycine in body fluids occur in propionic acidemia and methylmalonic acidemia that are collectively referred to as *ketotic hyperglycinemia* because episodes of severe acidosis and ketosis occur. The pathogenesis of hyperglycinemia in these disorders is not fully understood, but inhibition of the glycine cleavage enzyme system by the various organic acids has been shown to occur in some patients. The term *nonketotic hyperglycinemia* is reserved for the clinical condition caused by the genetic deficiency of the glycine cleavage enzyme system (Fig. 74–8). In this condition, hyperglycinemia is present without ketosis.

Nonketotic Hyperglycinemia (NKH).

Four forms of NKH have been identified: neonatal, infantile, late onset, and transient.

NEONATAL NKH.

This is the most common form of NKH. *Clinical manifestations* develop during the first few days of life

Figure 74.7-8 Pathways in metabolism of glycine and gloxylic acid. **Enzymes:** (1) glycine cleavage enzyme; (2) alanine:glyoxylate aminotransferase; (3) d-glyceric acid dehydrogenase; (4) glycerate kinase; (5) trimethylamine oxidase; (6) lactate dehydrogenase; (7) glycolate oxidase; (8) sarcosine dehydrogenase. NKH* = nonketotic hyperglycinemia; FH_4 = tetrahydrofolate.

(between 6?hr to 8 days after birth). Poor feeding, failure to suck, lethargy, and profound hypotonia may progress rapidly to a deep coma, apnea, and death. Convulsions, especially myoclonic seizures and hiccups, are common.

Laboratory findings include moderate to severe hyperglycinemia (as high as eight times normal) and hyperglycinuria. The unequivocal elevation of glycine concentration in the spinal fluid (15–30 times normal) and the high ratio of glycine concentration in spinal fluid to that in plasma (a value greater than 0.08) are diagnostic of NKH. Serum pH is normal; plasma serine levels are usually low.

About 30% of affected infants die despite supportive therapy. Those who survive develop profound psychomotor retardation and intractable seizure disorders (myoclonic and/or grand mal seizures).

INFANTILE NKH.

These previously normal infants develop *signs and symptoms* of neonatal NKH (see earlier) after 6 mo of age. Seizures are the common presenting signs. This condition appears to be a milder form; infants usually survive; mental retardation is not as profound as in the neonatal form.

Laboratory findings in these patients are identical to the neonatal form.

LATE-ONSET NKH.

This has been reported in a few patients. Progressive spastic paraparesis, optic atrophy, and choreoathetotic movements are the main *clinical manifestations*. Age at onset has been between 2 and 33 yr. Mental development is usually normal, but mild retardation has been reported in three patients. Seizures have occurred in only one patient.

Laboratory findings are similar to, but not as pronounced as in, the neonatal form.

TRANSIENT NKH.

This form has been described in six infants. Clinical and laboratory manifestations are indistinguishable from those of the neonatal form. However, by 2 to 8 wk of age, the elevated glycine levels in plasma and cerebrospinal fluid normalize and a complete clinical recovery occurs. Five of these patients had no neurologic abnormalities, but one had severe mental retardation. The etiology of this condition is not known but it is believed to be caused by immaturity of the enzyme system.

All forms of NKH should be differentiated from ketotic hyperglycinemia (see Chapter 74.6), d-glyceric aciduria (see later), and ingestion of valproic acid. The latter compound causes a moderate increase in blood and urinary glycine concentrations. Repeat assays after discontinuation of the drug should establish the diagnosis.

Diagnosis may be established by assay of the enzyme in liver or brain specimens. Enzyme activity in the neonatal form is close to zero, whereas in the other forms some residual activity is present. In over 80% of patients with the neonatal form, the enzyme defect resides in the P protein. The deficit in the remainder of these patients is in the T protein. The enzyme assay in three patients with the infantile and

late-onset forms revealed two patients with the defect in the T protein and one in the H protein.

No effective *treatment* is known. Exchange transfusion, dietary restriction of glycine, and administration of sodium benzoate or folate have not altered the neurologic outcome. Drugs that counteract the effect of glycine on neuronal cells, such as strychnine, diazepam, and dextromethorphan have shown some beneficial effects only in patients with the mild forms of the condition.

NKH is inherited as an autosomal recessive trait. The prevalence is not known, but the condition is quite common in northern Finland (1:12,000). The gene for P protein is located on the short arm of chromosome 9. The gene for H and T proteins are mapped to the long arm of chromosome 3. *Prenatal diagnosis* has been accomplished by performing an assay of the enzyme activity in chorionic villi biopsy specimens.

Sarcosinemia.

Increased concentrations of sarcosine (*N*-methylglycine) have been observed in both blood and urine, but no consistent clinical picture has been attributed to this metabolic defect. This is a recessively inherited inborn error involving sarcosine dehydrogenase, the enzyme that converts sarcosine to glycine (see Fig. 74–8). The gene for this enzyme is located on the long arm of chromosome 9.

d-Glyceric Aciduria.

d-Glyceric acid is an intermediate metabolite of serine and fructose metabolism (see Fig. 74–8). At least two forms of this rare condition have been identified. In one form, clinical manifestations of severe encephalopathy (hypotonia, seizures, and mental and motor deficits) and the laboratory findings of hyperglycinemia and hyperglycinuria were suggestive of nonketotic hyperglycinemia. However, these patients excreted large quantities of d-glyceric acid (this compound is not normally detectable in urine). Enzyme studies indicated a deficiency of glycerate kinase in one patient and decreased activity of d-glyceric dehydrogenase in another.

In the other form, the major findings are persistent metabolic acidosis and developmental delay. This infant excreted large amounts of d-glyceric acid without hyperglycinemia. The enzyme defect in this patient is not known.

No effective therapy is available. Restriction of fructose improved seizures in one patient.

Trimethylaminuria.

Trimethylamine is normally produced in the intestine from the breakdown of dietary choline and trimethylamine oxide by bacteria. Eggs and liver are the main sources of choline, and fish is the major source of trimethylamine oxide. Trimethylamine is absorbed and oxidized in the liver by trimethylamine oxidase to trimethylamine oxide, which is odorless, and is excreted in the urine (see Fig. 74–8). Deficiency of this enzyme results in massive excretion of trimethylamine in urine. Several asymptomatic patients with trimethylaminuria have been reported; there is a foul body odor that resembles that of a rotten fish, which may have significant social and psychosocial ramifications. Restriction of fish, eggs, liver, and other sources of choline (such as nuts and grains) in the diet significantly reduces the odor. The gene for trimethylamine oxidase has been mapped to the long arm of chromosome 1.

Hyperoxaluria and Oxalosis.

Normally, oxalic acid is derived mostly from oxidation of glyoxylic acid and, to a lesser degree, from oxidation of ascorbic acid (see Fig. 74–8). Glyoxylic acid is formed from the oxidation of glycolic acid in the peroxisomes. The source of glycolic acid remains unclear. Foods containing oxalic acid, such as spinach and rhubarb, are the main exogenous sources of this compound. Oxalic acid cannot be further metabolized in humans and is excreted in the urine as oxalates. Calcium oxalate is relatively insoluble in water and precipitates in tissues (kidneys and joints) if its concentration increases in the body.

Secondary hyperoxaluria has been observed in pyridoxine deficiency (cofactor for alanine-glyoxylate aminotransferase, see Fig. 74–8), after ingestion of ethylene glycol or high doses of vitamin C, after administration of the anesthetic agent methoxyflurane (which oxidizes directly to oxalic acid), and in patients with inflammatory bowel disease or extensive resection of the bowel *(enteric hyperoxaluria)*. Acute, fatal hyperoxaluria may develop after ingestion of plants with a high oxalic acid content, such as sorrel. Precipitation of calcium oxalate in tissues causes hypocalcemia, liver necrosis, renal failure, cardiac arrhythmia, and death. The lethal dose of oxalic acid is estimated to be 5–30?g.

Primary hyperoxaluria is a rare genetic disorder in which large amounts of oxalates accumulate in the body. Two types of primary hyperoxaluria have been identified. The term *oxalosis* refers to deposition of calcium oxalate in parenchymal tissue.

PRIMARY HYPEROXALURIA TYPE I.

This rare condition is the most common form of primary hyperoxaluria. It is caused by a deficiency of the peroxisomal enzyme alanine-glyoxylate

aminotransferase, which is expressed only in the liver peroxisomes and requires pyridoxine (vitamin B_6) as its cofactor. In the absence of this enzyme, glyoxylic acid, which cannot be converted to glycine, is transferred to the cytosol, where it is oxidized to oxalic acid (see Fig. 74–8). It is inherited as an autosomal recessive trait. The gene for this enzyme resides on the long arm of chromosome 2. Several mutations of the gene have been described in patients with this condition. The most common mutation results in the targeting of the enzyme to the mitochondria instead of the peroxisomes. The in vitro enzyme activity in these patients may reach the level found in obligate heterozygotes. However, in vivo function remains defective. About 30% of patients with hyperoxaluria type 1 are estimated to have this defect.

There is a wide variation in the age of presentation. The majority of patients become symptomatic before 5 yr of age. In about 10% of cases symptoms develop before 1 yr of age (neonatal oxaluria). The initial *clinical manifestations* are related to renal stones and nephrocalcinosis. Renal colic and asymptomatic hematuria lead to a gradual deterioration of renal function, manifested by growth retardation and uremia. Most patients die before 20 yr of age from renal failure if the disorder is untreated. Acute arthritis is a rare manifestation and may be misdiagnosed as gout because uric acid is usually elevated in patients with type I hyperoxaluria. Late forms of the disease presenting during adulthood have also been reported.

A marked increase in urinary excretion of oxalate (normal excretion, 10–50?mg/24?hr) is the most important *laboratory finding*. The presence of oxalate crystals in urinary sediment is rarely helpful for diagnosis because such crystals are often seen in normal individuals. Urinary excretion of glycolic acid and glyoxylic acid is increased. *Diagnosis* can be confirmed by performing an assay of the enzyme in liver specimens.

Medical treatment has been largely unsuccessful. In some patients administration of large doses of pyridoxine reduces urinary excretion of oxalate. Renal transplantation in patients with renal failure has not improved the outcome in most cases, because oxalosis has recurred in the transplanted kidney. Combined liver and kidney transplants have resulted in a significant decrease in plasma and urinary oxalate in a few patients and may be the most effective treatment of this disorder.

Prenatal diagnosis has been achieved by the measurement of fetal hepatic enzyme activity obtained by needle biopsy or by DNA analysis of chorionic villi samples.

PRIMARY HYPEROXALURIA TYPE II (L-GLYCERIC ACIDURIA).

This rare condition is due to a deficiency of D-glycerate dehydrogenase/glyoxylate reductase enzyme complex (see Fig. 74–8). A deficiency in the activity of this enzyme results in an accumulation of two intermediate metabolites, hydroxypyruvate (the ketoacid of serine) and glyoxylic acid. Both these compounds are further metabolized by lactate dehydrogenase (LDH) to L-glyceric acid and oxalic acid, respectively. Saulteaux-Ojibway Indians of Manitoba may have a higher risk of this condition.

Clinically, these patients are indistinguishable from those with hyperoxaluria type I. Renal stones presenting as renal colic and hematuria may develop before age 2 yr. Renal failure has not been observed in patients with type II oxaluria; the urine contains large amounts of L-glyceric acid in addition to high levels of oxalate (L-glyceric acid is not normally present in urine). Urinary excretion of glycolic acid and glyoxylic acid is not increased. The presence of L-glyceric acid without increased levels of glycolic and glyoxylic acids in urine differentiate this type from type I hyperoxaluria.

No effective *therapy* is available.

Creatine Deficiency (Guanidinoacetate Methyltransferase Deficiency).

Creatine is synthesized in the liver, pancreas, and kidneys from arginine and glycine (Fig. 74–9) and is transported to muscles and the brain, which contain high activities of creatine kinase. Phosphorylation and dephosphorylation of creatine by this enzyme in conjunction with adenosine diphosphate and triphosphate (ADP/ATP) provide high-energy phosphate reactions in these organs. Creatine is nonenzymatically metabolized to creatinine at a constant daily rate and is excreted in the urine. Deficiency of guanidinoacetate methyltransferase causes a severe creatine deficiency state.

Figure 74.7-9 Pathways for the synthesis of serine and creatine. **Enzymes:** (1) 3-phosphoglycerate dehydrogenase; (2) guanidinoacetate methyltransferase.

Clinical manifestations relate to the brain and muscles and may appear in the first few weeks or months of life. Developmental delay, mental retardation, absence of active speech, autistic behavior with self-mutilation, and profound hypertonia with dyskinetic and dystonic movements are found in most patients. Seizures are a common finding. Somatic growth is normal.

Laboratory findings include decreased creatine and creatinine in blood and urine. Marked elevations of guanidinoacetate in blood, urine, and especially cerebrospinal fluid, are diagnostic. Absence of creatine and creatine phosphate and high levels of guanidinoacetate can be demonstrated in the brain by magnetic resonance spectroscopy (MRS). MRI shows signal hyperintensity of the globus pallidus. *Diagnosis* may be confirmed by measurement of the enzyme in the liver, cultured fibroblasts, stimulated lymphoblasts, or DNA analysis of the gene.

Treatment with creatine monohydrate (350?mg–2?g/kg/day) orally has resulted in a dramatic improvement in muscle tone and mental development and has normalized MRI and electroencephalographic findings. Treatment has no effect on speech development. It is believed that early treatment may ensure normal development.

The condition is inherited as an autosomal recessive trait. The gene for guanidinoacetate methyltransferase has been mapped to the short arm of chromosome 19p13.3, and at least two disease-causing alleles have been identified. This condition must be considered in any patient with brain and muscle disorders, because treatment can produce a dramatic response.

74.8 Serine

Iraj Rezvani

Serine is a nonessential amino acid synthesized from glucose and glycine (see Fig. 74–9).

3-Phosphoglycerate Dehydrogenase Deficiency.

A small number of patients with this enzyme deficiency have been reported.

Clinical manifestations usually develop shortly after birth and include severe mental retardation, seizures, hypotonia, and microcephaly. Bilateral cataracts have been reported in at least one patient.

Laboratory findings include low fasting levels of serine and glycine in plasma and very low levels of serine (five times lower than normal) and glycine (two times lower than normal) in cerebrospinal fluid. No abnormal organic acid is found in the urine. MRI of the head shows evidence of cortical atrophy and dysmyelination.

Diagnosis can be confirmed by measurement of the enzyme activity in cultured fibroblasts.

Treatment with serine (200?mg/kg/24?hr, orally) normalizes the serine levels in the blood and in the cerebrospinal fluid. Seizure activity has stopped after 1 wk of treatment. The long-term effectiveness of treatment is unknown. The condition is presumably inherited as an autosomal trait. The gene for 3-phosphoglycerate dehydrogenase enzyme has been mapped to the long arm of chromosome 1. The favorable response of this condition to a simple treatment makes this diagnosis an important consideration in any child with neurologic defects such as psychomotor delay or a seizure disorder.

74.9 Proline and Hydroxyproline

Iraj Rezvani

Proline and hydroxyproline are found in high concentrations in collagen. Neither of these amino acids is normally found in urine in the free form except in early infancy. Excretion of “bound” hydroxyproline (dipeptides and tripeptides containing hydroxyproline) reflects collagen turnover and is increased in disorders of accelerated collagen turnover, such as rickets or hyperparathyroidism.

Hyperprolinemia.

Two types of this rare autosomal recessive condition have been described. *Type I hyperprolinemia* is due to a deficiency of proline oxidase (dehydrogenase), and *type II* is due to a defect in ?'-pyrroline-5-carboxylic acid dehydrogenase enzyme (Fig. 74–10). Neither type causes any specific clinical manifestation. Increased blood concentrations of proline (more pronounced in type II) and prolinuria are found in both types. Hydroxyproline and glycine are also excreted in abnormal amounts in the urine because of the saturation of the common tubular reabsorption mechanism by the massive prolinuria. The presence of ?'-pyrroline-5-carboxylic acid in plasma and urine differentiates type II from type I. No treatment is recommended for the affected individuals. A 20-mo-old infant with seizures has been found to have prolinuria type II with biochemical evidence of vitamin B_6 deficiency. Seizures responded to vitamin B_6 therapy. The causal relationships between prolinuria type II, vitamin B_6 deficiency, and seizures are unclear.

Hyperhydroxyprolinemia.

This rare autosomal recessive condition is presumably caused by a deficiency of hydroxyproline oxidase (see Fig. 74–10). Patients with this disorder are usually asymptomatic. A marked increase in blood concentration of hydroxyproline is diagnostic. These patients also excrete large quantities of proline and glycine in their urine. No treatment is recommended.

Prolidase Deficiency.

During collagen degradation imidodipeptides (such as glycylproline) are released and are normally cleaved by tissue prolidase. This enzyme requires manganese for its proper activity. Deficiency of prolidase, which is inherited as an autosomal recessive trait, results in the accumulation of imidodipeptides in body fluids.

The *clinical manifestations* of this rare condition and the age at onset are quite variable (19 mo to 19 yr) and include recurrent, painful skin ulcers, which are typically on hands and legs. Other

Figure 74.9-10 Pathways in the metabolism of proline. **Enzymes:** (1) proline oxidase; (2) ?'-pyrroline-5-carboxylic acid dehydrogenase; (3) hydroxyproline oxidase.

skin lesions that may precede ulcers by several years may include scaly erythematous maculopapular rash, purpura, and telangiectasia. Most ulcers become infected. Healing of the ulcers may take 4–7 mo. Mild to severe mental and motor deficits and susceptibility to infections are also present in most patients (recurrent otitis media, sinusitis, respiratory infection, splenomegaly). Infection is the cause of death. Some patients may have some craniofacial abnormalities such as ptosis, ocular proptosis, and prominent cranial sutures. Asymptomatic cases have also been reported. High levels of urinary excretion of imidodipeptides are diagnostic. Enzyme assay may be performed in erythrocytes or cultured skin fibroblasts.

Oral supplementation with proline, ascorbic acid, and manganese and the topical use of proline and glycine result in an improvement in leg ulcers. These treatments are not consistently effective in all patients.

The gene for prolidase enzyme has been mapped to the long arm of chromosome 19q12-13.11, and several disease-causing mutations have been identified in different families

74.10 Glutamic Acid

Iraj Rezvani

Glutathione (?-glutamylcysteinylglycine) is the major product of glutamic acid in the body. This ubiquitous tripeptide is synthesized and degraded through a complex cycle called the ?-glutamyl cycle (Fig. 74–11). Because of its free sulfhydryl (-SH) group and its abundance in the cell, glutathione protects other sulfhydryl-containing compounds (such as enzymes and coenzyme A) from oxidation. It is also involved in the detoxification of peroxides, including hydrogen peroxide, and in keeping the cell in a reduced state. The common consequence of glutathione deficiency is hemolytic anemia. Glutathione also participates in amino acid transport across the cell membrane through the ?-glutamyl cycle.

Glutathione Synthetase Deficiency (see Part XX , Section 3 and Fig. 74–11).

Two forms of this condition have been reported. In the *severe form*, which is due to generalized deficiency of the enzyme, severe acidosis and massive 5-oxoprolinuria are the rule. In the *mild form*, in which the enzyme deficiency causes glutathione deficiency only in the red blood cells, neither 5-oxoprolinuria nor acidosis is observed. In both forms, patients have hemolytic anemia secondary to glutathione deficiency.

GLUTATHIONE SYNTHETASE DEFICIENCY, SEVERE FORM (PYROGLUTAMIC ACIDEMIA, SEVERE 5-OXOPROLINURIA).

Clinical manifestations of this rare condition occur in the first few days of life and include metabolic acidosis, jaundice, and mild to moderate hemolytic anemia. Chronic acidosis continues after recovery. Similar episodes of life-threatening acidosis may occur during gastroenteritis or infection or after a surgical procedure. In a subgroup of patients, mental retardation and neurologic deficits such as spastic tetraparesis, ataxia, tremor, dysarthria, and seizures are present. Susceptibility to

Figure 74.10-11 The ?-glutamyl cycle. Defects of glutathione synthesis and degradation are noted. **Enzymes:** (1) ?-glutamyl transpeptidase; (2) ?-glutamyl cyclotransferase; (3) 5-oxoprolinase; (4) ?-glutamylcysteine synthetase; (5) glutathione synthetase; (6) glutamic acid decarboxylase; (7) GABA transaminase; (8) succinic semialdehyde dehydrogenase.

infection, presumably caused by granulocyte dysfunction, is observed in a few patients.

Laboratory findings include metabolic acidosis, mild to moderate degrees of hemolytic anemia and massive amounts (up to 40?g/24?hr) of 5-oxoprolinuria. High concentrations of this compound are also found in blood. The glutathione content of erythrocytes is markedly decreased. Increased synthesis of 5-oxoproline in this disorder is believed to be caused by the conversion of ?-glutamylcysteine to 5-oxoproline by the enzyme ?-glutamyl cyclotransferase (see Fig. 74–11). ?-Glutamylcysteine production increases greatly because the normal inhibitory effect of glutathione on the ?-glutamylcysteine synthetase enzyme is removed. A deficiency of glutathione synthetase has been demonstrated in a variety of cells including erythrocytes.

Treatment of acute attack includes hydration, correction of acidosis (by infusion of sodium bicarbonate), and measures to correct anemia and hyperbilirubinemia. Chronic administration of alkali is usually needed. Administration of large doses of vitamins C and E is recommended. Drugs and oxidants that are known to cause hemolysis and stressful catabolic states should be avoided. Oral administration of glutathione analogues has had variable success.

Prenatal diagnosis can be achieved by the measurement of 5-oxoproline in amniotic fluid, by enzyme analysis in cultured amniocytes or chorionic villi samples, or by DNA analysis of the gene. Successful pregnancy in affected females with favorable outcomes for both mothers and infants is reported.

The condition is inherited as an autosomal recessive trait. The gene for this enzyme is located on the long arm of chromosome 20q11.2. Several disease-causing mutations have been identified in different families.

GLUTATHIONE SYNTHETASE DEFICIENCY, MILD FORM.

This form has been reported only in a few patients. Mild to moderate hemolytic anemia has been the only *clinical finding* in these patients. Splenomegaly has been reported in patients. Mental development is normal; metabolic acidosis and increased concentrations of 5-oxoproline do not occur. This condition is due to mutations in the gene that encodes for glutathione synthetase enzyme. These mutations presumably render the enzyme unstable but with normal catalytic function. The expedited rate of enzyme turnover caused by these mutations is of no consequence for all tissues with normal protein synthesis except for erythrocytes in which the absence of protein synthesis results in a serious deficiency of glutathione. *Treatment* is that of hemolytic anemia and avoidance of drugs and oxidants that can trigger the hemolytic process.

5-Oxoprolinase Deficiency (5-oxoprolinuria).

The main cause of massive 5-oxoprolinuria is glutathione synthetase deficiency (see earlier). Moderate 5-oxoprolinuria has been found in a variety of metabolic and acquired conditions, such as in patients with severe burns, Stevens-Johnson syndrome, homocystinuria, urea cycle defects, and tyrosinemia type I.

A few individuals with moderate 5-oxoprolinuria (4–10?g/ day) due to 5-oxoprolinase deficiency have been identified. No specific clinical picture has yet emerged. Moderate to severe mental retardation has been reported in two patients. However, asymptomatic individuals with the enzyme deficiency have also been identified. It is, therefore, not clear whether 5-oxoprolinase deficiency is of any clinical consequence. No treatment has been recommended.

?-Glutamylcysteine Synthase Deficiency.

Only a few patients with this enzyme deficiency have been reported. The most consistent clinical manifestation has been mild chronic hemolytic anemia. Acute attacks of hemolysis have occurred after exposure to sulfonamides. Peripheral neuropathy and progressive spinocerebellar degeneration have been noted in two siblings in adulthood. Laboratory findings of chronic hemolytic anemia were present in all patients. Two patients had generalized aminoaciduria because the ?-glutamyl cycle is involved in amino acid transport in cells (see Fig. 74–11). *Treatment* is that of hemolytic anemia. The condition is inherited as an autosomal recessive trait.

GLUTATHIONEMIA (?-GLUTAMYL TRANSPEPTIDASE (GGT) DEFICIENCY).

This enzyme is present in any cell that has secretory or absorptive functions. It is especially abundant in the kidneys, pancreas, intestines, and liver. The enzyme is also present in the bile. Measurement of this enzyme in the blood is commonly performed to evaluate liver and bile duct diseases.

Deficiency of this enzyme causes an elevation in glutathione concentrations in body fluids, but cellular levels remain normal. Only a few patients with enzyme deficiency have been reported; therefore, the scope of *clinical manifestations* is not well defined. Mild to moderate mental retardation and severe behavioral problems were observed in three patients. One of the two sisters with this condition had normal intelligence as an adult and the other had Prader-Willi syndrome.

Laboratory findings include marked elevations in urinary concentrations of glutathione (up to 1?g/day), ?-glutamylcysteine, and cysteine. None of the reported patients has had generalized aminoaciduria, a finding that would have been expected to occur in this enzyme deficiency (see Fig. 74–11).

Diagnosis can be confirmed by measurement of the enzyme activity in leukocytes or cultured skin fibroblasts. No effective *treatment* is available.

The condition is inherited as an autosomal recessive trait. The enzyme GGT is a complex protein and is coded by several genes (at least seven). Most of the genes are located on the long arm of chromosome 22.

Inborn Errors of Metabolism of ?-Aminobutyric Acid (GABA).

Decarboxylation of glutamic acid by glutamic acid decarboxylate (GAD) is the main biosynthetic pathway for GABA production in the brain and other organs, especially kidneys and the beta cells of the pancreas. This enzyme requires pyridoxine (vitamin

B_6) as a cofactor (see Fig. 74–11). Two GAD enzymes (GAD_{65} and GAD_{67}) have been identified. GAD_{67} is the main enzyme in the brain, and GAD_{65} is the major one in the beta cells. Antibodies against GAD_{65} and GAD_{67} are the major markers for type I diabetes and stiff-man syndrome, respectively. The gene for GAD_{65} is mapped to the short arm of chromosome 10p11-23 and that for GAD_{67} to the long arm of chromosome 2q31.

PYRIDOXINE (VITAMIN B_6) DEPENDENCY WITH SEIZURES (also see Chapter 95).

This autosomal recessive condition is due to GABA deficiency in the brain, which is presumably caused by decreased activity of glutamic acid decarboxylase (GAD). The main *clinical manifestation* of this condition is seizures, which usually occur in the first few hours of life and are unresponsive to conventional anticonvulsant therapy. Administration of vitamin B_6 in large doses (10–100?mg/kg) usually results in a dramatic improvement of both seizures and electroencephalographic abnormalities. Late-onset forms of the condition (as late as 2 yr of age) have also been reported. A trial with vitamin B_6 therapy has, therefore, been recommended in any infant with intractable seizures. The dependency is usually life long. Other neurologic findings such as delayed speech are noted in some patients.

Laboratory findings include increased glutamate and decreased GABA levels in the brain and in the spinal fluid.

The pathogenesis of this condition remains unclear. Although an increase in the Km of the GAD enzyme for its cofactor (vitamin B_6) in the brain seems a logical explanation, no abnormality in the GAD activity in the brain has been documented. DNA studies of the gene for GAD_{65} and GAD_{67} have also revealed no mutations. Linkage studies have mapped the condition to the long arm of chromosome 5q31.2, a locus completely different from loci of GAD enzymes.

Treatment with high daily doses of vitamin B_6 is necessary indefinitely.

GABA TRANSAMINASE DEFICIENCY.

This is a very rare autosomal recessive condition that has been reported in three infants from two different families. *Clinical manifestations* include severe psychomotor retardation, hypotonia, hyperreflexia, lethargy, and refractory seizures. Increased linear growth was present in the original report of two siblings. Increased concentrations of GABA and ß-alanine are found in the spinal fluid. Evidence of leukodystrophy is noted in the postmortem examination of the brain. GABA transaminase deficiency is demonstrated in the brain and lymphocytes. No effective treatment is available. Treatment with vitamin B_6 (natural cofactor of the enzyme) has been ineffective.

?-HYDROXYBUTYRIC ACIDURIA (SUCCINIC SEMI-ALDEHYDE DEHYDROGENASE DEFICIENCY).

Over 150 patients with this enzyme deficiency (see Fig. 74–11) have been reported. *Clinical manifestations*, which usually begin in early infancy, include mild to moderate mental retardation, delayed speech, marked hypotonia, ataxia, and seizures. Other associated findings are oculomotor apraxia, choreoathetosis, autistic features, and aggressive behavior. Ataxia may improve with advancement of age.

Laboratory findings include marked elevations in ?-hydroxybutyric acid concentrations in the blood (up to 200-fold), spinal fluid (up to 1200-fold), and urine (up to 800-fold). There is no acidosis. Urinary excretion of ?-hydroxybutyric acid decreases with age. Increased concentrations of glycine may also be present in plasma, urine, and spinal fluid.

Diagnosis can be confirmed by measurement of the enzyme activity in lymphocytes. *Prenatal diagnosis* has been achieved by measurement of ?-hydroxybutyric acid in the amniotic fluid and assay of the enzyme activity in the amniocytes or in biopsy specimens of chorionic villi.

Treatment has been largely ineffective; vigabatrin has produced some improvement in ataxia and the mental status in some patients.

The condition is inherited as an autosomal recessive trait. The gene for succinic semialdehyde dehydrogenase has been mapped to the short arm of chromosome 6p22.

The role of ?-hydroxybutyric acid in the pathogenesis of this condition remains unclear and somewhat confusing because administration of this compound to humans and animals has produced some opposite effects. ?-Hydroxybutyrate (GHB) has been used illicitly as a recreational drug with anesthetic effect and is a “date-rape” drug (also see chapter 105).

74.11 Urea Cycle and Hyperammonemia (Arginine, Citrulline, Ornithine)

Iraj Rezvani

Catabolism of amino acids produces free ammonia, which is highly toxic to the central nervous system. Ammonia is detoxified to urea through a series of reactions known as the Krebs-Henseleit or urea cycle (Fig. 74–12). Five enzymes are required for the synthesis of urea: carbamyl phosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinate synthetase (AS), argininosuccinate lyase (AL), and arginase. A sixth enzyme, *N*-acetylglutamate synthetase, is also required for synthesis of *N*-acetylglutamate, which is an activator of the CPS enzyme. Individual deficiencies of these enzymes have been observed; and, with an overall prevalence of 1 in 30,000 live births, they are the most common genetic causes of hyperammonemia in infants.

Genetic Causes of Hyperammonemia.

In addition to defects of the urea cycle enzymes, a marked increase in plasma level of ammonia is also observed in other inborn errors of metabolism (Box 74–1).

Clinical Manifestations of Hyperammonemia.

In the *neonatal period*, symptoms and signs are mostly related to brain dysfunction and are similar regardless of the cause of the hyperammonemia. The affected infant is normal at birth but becomes symptomatic within a few days of protein feeding. Refusal to eat, vomiting, tachypnea, and lethargy quickly progress to a deep coma. Convulsions are common. Physical examination may reveal hepatomegaly and neurologic signs of deep coma. In *infants and older children*, acute hyperammonemia is manifested by vomiting and neurologic abnormalities such as ataxia, mental confusion, agitation, irritability, and combativeness. These manifestations may alternate with periods of lethargy and somnolence that may progress to coma.

Routine *laboratory studies* show no specific findings when hyperammonemia is due to defects of the urea cycle enzymes. Blood urea nitrogen is usually low. Serum pH is usually normal or mildly elevated. In infants with organic acidemias, hyperammonemia is commonly associated with severe acidosis. Newborn infants with hyperammonemia are often misdiagnosed as having sepsis; they may succumb without a correct diagnosis. Autopsy is usually unremarkable. It is therefore imperative to measure plasma ammonia levels in any ill infant whose clinical manifestations cannot be explained by an obvious infection.

Diagnosis.

The main criterion for diagnosis is hyperammonemia. The plasma ammonia concentration in the ill infant is usually above 200?µM (normal values <35?µM). An approach to the differential diagnosis of hyperammonemia in the newborn infant is illustrated in Figure 74–13 . Patients with a deficiency of carbamyl phosphate synthetase or of ornithine transcarbamylase have no specific abnormalities of plasma amino acids except for increased levels of glutamine, aspartic acid, and alanine secondary to hyperammonemia. A marked increase in urinary orotic acid in patients with ornithine transcarbamylase deficiency differentiates this defect from carbamyl phosphate synthetase deficiency. Patients with a deficiency of argininosuccinic acid synthetase, argininosuccinic acid lyase, or arginase have a marked increase in the plasma level of citrulline, argininosuccinic acid, or arginine, respectively. Differentiation between the carbamyl phosphate synthetase deficiency and the *N*-acetylglutamate synthetase deficiency may require an assay of the respective enzymes. Clinical improvement occurring after oral administration of carbamylglutamate, however, may suggest *N*-acetylglutamate synthetase deficiency.

Treatment of Acute Hyperammonemia.

Acute hyperammonemia should be treated promptly and vigorously. The goal of therapy

Box 74.11-1. Inborn Errors of Metabolism Causing Hyperammonemia

- Deficiencies of the urea cycle enzymes
  - Carbamyl phosphate synthetase (CPS)
  - Ornithine transcarbamylase (OTC)
  - Argininosuccinate synthetase (AS)
  - Argininosuccinate lyase (AL)
  - Arginase
  - *N*-Acetylglutamate synthetase
- Organic acidemias
  - Propionic acidemia
  - Methylmalonic acidemia
  - Isovaleric acidemia
  - ß-Ketothiolase deficiency
  - Multiple carboxylase deficiencies
  - Medium chain fatty acid acyl CoA dehydrogenase deficiency
  - Glutaric acidemia type II
  - 3-Hydroxy-3-methylglutaric aciduria
- Lysinuric protein intolerance
- Hyperammonemia-hyperornithinemia-homocitrullinemia syndrome
- Transient hyperammonemia of the newborn
- Congenital hyperinsulinism with hyperammonemia

Figure 74.11-12 Urea cycle: pathways for ammonia disposal and ornithine metabolism. Reactions occurring in the mitochondria are depicted in purple. Reactions shown with interrupted arrows are the alternate pathways for the disposal of ammonia. **Enzymes:** (1) carbamylphosphate synthetase (CPS); (2) ornithine transcarbamylase (OCT); (3) argininosuccinic acid synthetase; (4) argininosuccinic acid lyase; (5) arginase; (6) ornithine 5-aminotransferase; (7) *N*-acetylglutamate synthetase. *HHH syndrome: hyperammonemia-hyperornithinemia-homocitrullinemia.

is to remove ammonia from the body and to provide adequate calories and essential amino acids to halt further breakdown of endogenous proteins (Box 74–2). Adequate calories, fluid, and electrolytes should be provided intravenously. Lipids for intravenous use (1?g/kg/24?hr) provide an effective source of calories. Minimal amounts of protein (0.25?g/kg/24?hr), preferably in the form of essential amino acids, should be added to the intravenous fluid to prevent a catabolic state. Oral feeding with a low-protein formula (0.5–1.0?g/kg/24?hr) through a nasogastric tube should be started as soon as sufficient clinical improvement is seen.

Because the kidneys clear ammonia poorly, its removal from the body must be expedited by formation of compounds with a high renal clearance. Sodium benzoate forms hippuric acid with endogenous glycine (see Fig. 74–12). Each mole of benzoate removes 1 mole of ammonia as glycine. Phenylacetate conjugates with glutamine to form phenylacetylglutamine, which is readily excreted in the urine. One mole of phenylacetate removes 2 moles of ammonia as glutamine from the body (see Fig. 74–12).

Arginine administration is effective in the treatment of hyperammonemia that is due to defects of the urea cycle (except in patients with arginase deficiency) because it supplies the urea cycle with ornithine and *N*-acetylglutamate (see Fig. 74–12). In patients with citrullinemia, 1 mole of arginine reacts with 1 mole of ammonia (as carbamyl phosphate) to form citrulline. In patients with argininosuccinic acidemia, 2 moles of ammonia (as carbamyl phosphate and aspartate) react with arginine to form argininosuccinic acid. Citrulline and argininosuccinic acid are far less toxic and more readily excreted by the kidneys than ammonia. In patients with CPS or ornithine transcarbamylase (OTC) deficiency, arginine administration is indicated because arginine becomes an essential amino acid in these disorders. Patients with OTC deficiency benefit from citrulline supplementation (200?mg/kg/24?hr) because 1 mole of citrulline can accept 1 mole of ammonia (as aspartic acid) to form arginine. Obviously, in patients with arginase deficiency, administration of arginine or citrulline is contraindicated. Arginase deficiency is a rare condition in which acute hyperammonemia rarely occurs as a presenting sign. In patients whose hyperammonemia is secondary to organic acidemias, treatment with arginine is not indicated because no beneficial effect from such therapy can be expected. However, in a newborn infant with a first attack of hyperammonemia, arginine should be used until the diagnosis is established.

Benzoate, phenylacetate, and arginine may be administered together for maximal therapeutic effect. A priming dose of these compounds is followed by continuous infusion until recovery

Figure 74.11-13 Clinical approach to a newborn infant with symptomatic hyperammonemia. *HHH syndrome = hyperammonemia-hyperornithinemia-homocitrullinemia.

from the acute state occurs (see Box 74–2). It should be noted that both benzoate and phenylacetate are supplied as concentrated solutions and should be properly diluted (1–2% solution) for intravenous use. The recommended therapeutic doses of both compounds deliver a substantial amount of sodium to the patient that should be calculated as part of the daily sodium requirement. Benzoate and phenylacetate should be used with

Box 74.11-2. Treatment of Acute Hyperammonemia in an Infant

1. Provide adequate calories, fluid, and electrolytes intravenously (10% glucose and intravenous lipids 1?g/kg/24?hr). Add minimal amounts of protein preferably as a mixture of essential amino acids (0.25?g/kg/24?hr) during the first 24?hr of therapy.
2. Give priming doses of the following compounds:

    To be added to 20?mL/kg of 10% glucose and infused within 1–2?hr

    Sodium benzoate 250?mg/kg (5.5?g/nm^2)[*]

    Sodium phenylacetate 250?mg/kg (5.5?g/nm^2)[*]

    Arginine hydrochloride 200–600?mg/kg (4.0–12.0?g/nm^2) as a 10% solution

3. Continue infusion of sodium benzoate[*] (250–500?mg/kg/24?hr), sodium phenylacetate[*] (250–500?mg/kg/24?hr), and arginine (200–600?mg/kg/24?hr[†]) following the above priming doses. These compounds should be added to the daily intravenous fluid.
4. Initiate peritoneal dialysis or hemodialysis if above treatment fails to produce an appreciable decrease in plasma ammonia.

These compounds should be added to the daily intravenous fluid.
4. Initiate peritoneal dialysis or hemodialysis if above treatment fails to produce an appreciable decrease in plasma ammonia.

These compounds are usually prepared as a 1–2% solution for intravenous use. Sodium from these drugs should be included as part of the daily sodium requirement.

† *The higher dose is recommended in the treatment of patients with citrullinemia and argininosuccinic aciduria. Arginine is not recommended in patients with arginase deficiency and in those whose hyperammonemia is secondary to organic acidemia.*

caution in newborn infants with hyperbilirubinemia because they may potentiate the risk of indirect hyperbilirubinemia by displacing bilirubin from albumin. In infants at risk, it is advisable to reduce bilirubin to a safe level before administering benzoate or phenylacetate.

If the foregoing therapies fail to produce any appreciable change in the blood ammonia level within a few hours, hemodialysis or peritoneal dialysis should be used. Exchange transfusion has little effect on reducing total body ammonia. It should be used only if dialysis cannot be employed promptly or when the patient is a newborn infant with hyperbilirubinemia (see earlier). Hemodialysis, although the most effective measure for removal of ammonia, is technically difficult to perform and may not be readily available. Peritoneal dialysis, therefore, is the most practical and expeditious method for treatment of patients with severe hyperammonemia; there is usually a dramatic decrease in the plasma ammonia level within a few hours of dialysis, and in most patients the plasma ammonia returns to normal within 48?hr of initiation of peritoneal dialysis. In a patient whose hyperammonemia is due to an organic acidemia, peritoneal dialysis effectively removes both the offending organic acid and ammonia from the body.

To curtail the possible production of ammonia by intestinal bacteria, oral administration of neomycin and lactulose through a nasogastric tube should be initiated very early in the course of therapy. There may be considerable lag between the normalization of ammonia and an improvement in the neurologic status of the patient. Several days may be needed before the infant becomes fully alert.

LONG-TERM THERAPY.

Once the infant is alert, therapy should be tailored to the underlying cause of the hyperammonemia. In general, all patients require some degree of protein

restriction (1–2?g/kg/24?hr) regardless of the enzymatic defect. In patients with defects in the urea cycle, chronic administration of benzoate (250–500?mg/kg/24?hr), phenylacetate (250–500?mg/kg/24?hr), and arginine (200–400?mg/kg/24?hr) or citrulline (in patients with OTC deficiency, 200–400?mg/kg/24?hr) is effective in maintaining blood ammonia levels within the

normal range. Phenylbutyrate may be used in place of phenylacetate, because the patient and the family may not accept the latter owing to its offensive odor. Carnitine supplementation has also been recommended for treatment of these patients because benzoate and phenylacetate may cause carnitine depletion, but the clinical benefits of this compound remain to be proved. Catabolic states triggering hyperammonemia should be avoided.

Carbamylphosphate Synthetase (CPS) and N-Acetylglutamate Synthetase Deficiencies (see Fig. 74–12).

Deficiencies of these two enzymes produce similar *clinical and biochemical manifestations*. There is a wide variation in severity of symptoms and in the age of presentation. Most commonly the affected infant becomes symptomatic during the first few days of life with signs and symptoms of hyperammonemia (refusal to eat, vomiting, lethargy, convulsion, and coma). Late forms (as late as 32 yr of age) may present as an acute bout of hyperammonemia in a seemingly normal individual. Coma and death may occur during these episodes. Intermediate forms with mental retardation and chronic subclinical hyperammonemia interspersed with bouts of acute hyperammonemia have also been observed.

Laboratory findings include hyperammonemia without an increase in any specific amino acids in plasma; marked elevations in plasma concentrations of glutamine and alanine seen in these patients are secondary to hyperammonemia. Urinary orotic acid is usually low or may be absent (see Fig. 74–13).

Treatment of patients with CPS deficiency is similar to that outlined earlier for hyperammonemia. Patients with *N*-acetylglutamate synthetase deficiency were shown to benefit from oral administration of carbamylglutamate. It is therefore important to differentiate between these two enzyme deficiencies by assay of the enzyme activities in biopsy specimens obtained from the liver. Deficiency of this enzyme has rarely been documented in North America.

CPS deficiency is inherited as an autosomal recessive trait; the enzyme is normally present in the liver and intestine. The gene is mapped to the long arm of chromosome 2q35. Several disease-causing mutations have been found in different families.

Ornithine Transcarbamylase (OTC) Deficiency (see Fig. 74–12).

In this X-linked partially dominant disorder the hemizygote males are more severely affected than heterozygote females. The heterozygous females may have a mild form of the disease but the majority (about 75%) are asymptomatic. This is the most common form of the urea cycle disorders.

Clinical manifestations in a male newborn infant are usually those of severe hyperammonemia (see earlier) occurring in the first few days of life. In these patients, the prognosis is poor. Milder forms of the condition are commonly seen in heterozygous females and in some affected males. *Mild* forms characteristically have episodic manifestations, which may occur at any age (usually after infancy). Episodes of hyperammonemia (manifested by vomiting and neurologic abnormalities such as ataxia, mental confusion, agitation, and combativeness) are separated by periods of wellness. These episodes usually occur following a high-protein diet or as a result of a catabolic state such as infection. Hyperammonemic coma and death may occur during one of these attacks. Mental development may proceed normally in mildly affected patients. However, mild to moderate mental retardation is common. Gallstones have been seen in the survivors; the mechanism remains unclear.

The major *laboratory finding* during the acute attack is hyperammonemia without an increase in any specific amino acid in the blood. Elevation of the plasma concentrations of glutamine and alanine are secondary to hyperammonemia. A marked increase in the urinary excretion of orotic acid differentiates this condition from CPS deficiency (see Fig. 74–13). Orotates may precipitate in urine as gravel or stones. In the mild form, these laboratory abnormalities may revert to normal between attacks. This form should be differentiated from all the episodic conditions of childhood and from poisoning. In particular, lysinuric protein intolerance (see Chapter 74.13) mimics the clinical and biochemical characteristics of OTC deficiency. Increased urinary excretions of lysine, ornithine, and arginine and elevated blood concentrations of citrulline, which are salient features of lysinuric protein intolerance, are not seen in patients with OTC deficiency.

The *diagnosis* may be confirmed by performing an assay of enzyme activity that is normally present only in the liver. *Prenatal diagnosis* has been achieved by means of fetal liver biopsy and by DNA studies of chorionic villi samples. Using an oral protein load, which increases plasma ammonia and urinary orotic acid levels, may identify asymptomatic heterozygous female carriers. A marked increase in urinary excretion of orotidine after an allopurinol-loading test has also been used to detect obligate female carriers. Asymptomatic female carriers usually have mild cerebral dysfunction compared with their unaffected siblings.

Treatment is similar to that described for CPS deficiency except that citrulline may be used in place of arginine. Liver transplantation has been successful as a definite treatment in some patients with OTC deficiency.

The gene for ornithine transcarboxylase has been mapped to the short arm of X chromosome. Many disease-causing mutations (over 150) have been identified in different patients. The degree of enzyme deficiency and the genotype dictate the severity of the phenotype in most cases.

Argininosuccinic Acid Synthetase Deficiency (Citrullinemia) (see Fig. 74–12).

This disorder shows considerable clinical and biochemical heterogeneity. The spectrum of clinical manifestations ranges from severe forms to asymptomatic ones. The signs and symptoms in the neonatal form are identical to those seen in the severe forms of CPS and OTC deficiencies (see earlier). Mild forms may have a gradual onset with failure to thrive, frequent vomiting, developmental delay, and dry, brittle hair or, like mild forms of OTC deficiency, may appear episodically (see earlier). In some patients symptoms may not appear until 20 yr of age.

Laboratory findings are similar to those found in patients with OTC deficiency except that the plasma citrulline concentration is markedly elevated in patients with citrullinemia (see Fig. 74–13). Urinary excretion of orotic acid is moderately increased in patients with citrullinemia, and crystalluria from precipitation of orotates may also occur. Patients with argininosuccinic aciduria also show some increase in

the plasma concentration of citrulline in addition to elevated levels of argininosuccinic acid. The *diagnosis* is confirmed by performing an assay of the enzyme activity in cultured fibroblasts. *Prenatal diagnosis* is based on an assay of the enzyme activity in cultured amniotic cells.

Treatment is similar to that for other urea cycle disorders (see earlier). Although *prognosis* is very poor for symptomatic neonates, patients with the mild disease usually do well on a protein-restricted diet. Mild to moderate mental deficiency is a common sequela, even in a well-treated patient.

Citrullinemia is inherited as an autosomal recessive trait. The gene is located on the long arm of chromosome 9q34. Several disease-causing mutations have been identified in different families. The majority of patients are compound heterozygotes for two different alleles.

Argininosuccinate Lyase Deficiency (Argininosuccinic Aciduria) (see Fig. 74–12).

This deficiency is inherited as an autosomal recessive trait with a prevalence of about 1 in 70,000 live births. The gene is located on the long arm of chromosome 7.

The severity of the *clinical and biochemical manifestations* varies considerably. In the neonatal form, severe hyperammonemia develops in the first few days of life and mortality is usually high. In the subacute or late form the major finding is mental retardation, which is associated with failure to thrive and hepatomegaly. Abnormalities of the hair (characterized by dryness and brittleness) are of special diagnostic value. Microscopically, the hair appears similar to that seen in patients with trichorrhexis nodosa. Less severe hair abnormalities are also seen in patients with citrullinemia. Gallstones have been seen in some of the survivors. Acute attacks of severe hyperammonemia commonly occur during a catabolic state.

Laboratory findings include hyperammonemia, moderate elevations in liver enzymes, nonspecific increases in plasma levels of glutamine and alanine, moderate increase in plasma levels of citrulline (less than that seen in citrullinemia), and marked increase in plasma levels of argininosuccinic acid (see Fig. 74–13). In most amino acid analyzers, argininosuccinic acid appears within the isoleucine or methionine region, which may cause confusion in the diagnosis. Argininosuccinic acid can also be found in large amounts in urine and spinal fluid. The levels in the spinal fluid are usually higher than those in plasma. The enzyme is normally present in erythrocytes, the liver, and cultured fibroblasts. *Prenatal diagnosis* is based on measuring the enzyme activity in cultured amniotic cells. Argininosuccinic acid is also elevated in the amniotic fluid of affected fetuses.

Treatment is similar to that described for citrullinemia. Persistent hepatomegaly with mild increases in liver enzymes and bleeding tendencies caused by abnormal clotting factors are common sequelae of the disease.

Arginase Deficiency (Hyperargininemia) (see Fig. 74–12).

This defect is inherited as an autosomal recessive trait. There are two genetically distinct arginases in humans. One is cytosolic and is expressed in the liver and erythrocytes, and the other one is found in the renal mitochondria. The cytosolic enzyme, which is the one deficient in patients with arginase deficiency, is mapped to the long arm of chromosome 6q23. Several disease-causing mutations have been identified in different patients.

The *clinical manifestations* of this rare condition are quite different from those of other urea cycle enzyme defects. The onset is insidious; the infant usually remains asymptomatic in the first few months or, sometimes, years of life. A progressive spastic diplegia with scissoring of the lower extremities, choreoathetoid movements, and loss of developmental milestones in a previously normal infant may suggest a degenerative disease of the central nervous system. Two children were observed for several years with the diagnosis of cerebral palsy before the diagnosis of arginase deficiency was confirmed. Mental retardation is progressive; seizures are common but episodes of severe hyperammonemia are not usually seen in this disorder. Hepatomegaly may be present.

Laboratory findings include marked elevations of arginine in plasma and cerebrospinal fluid (see Fig. 74–13). Urinary orotic acid levels are moderately increased. Plasma ammonia levels may be normal or mildly elevated. Urinary excretions of arginine, lysine, cystine, and ornithine are usually increased, but normal levels have also been noted. Therefore, determination of amino acids in plasma is a critical step in the diagnosis of argininemia. The guanidino compounds (a-keto-guanidinovaleric acid, argininic acid) are markedly increased in urine. The *diagnosis* is confirmed by assaying arginase activity in erythrocytes. Prenatal diagnosis has been achieved.

Treatment consists of a low-protein diet devoid of arginine. Administration of a synthetic protein made of essential amino acids usually results in a dramatic decrease in plasma arginine concentration and an improvement in neurologic abnormalities. The composition of the diet and the daily intake of protein should be monitored by frequent plasma amino acid determinations. Sodium benzoate (250–375?mg/kg/24?hr) is also effective in controlling hyperammonemia. One patient developed type 1 diabetes at age 9 yr while the argininemia was under good control.

Transient Hyperammonemia of the Newborn.

Although plasma levels of ammonia in healthy, full-term infants are within normal limits, very low birthweight infants may have a *mild transient hyperammonemia* (40–50?µM), which lasts for 6–8 wk. These infants are asymptomatic, and follow-up studies up to 18 mo of age have not revealed any significant neurologic deficits.

Severe transient hyperammonemia has been observed in newborn infants. The majority of affected infants are premature and have mild respiratory distress syndrome. Hyperammonemic coma may develop within 2–3 days of life, and the infant may succumb to the disease if treatment is not started immediately.

Laboratory studies reveal marked hyperammonemia (plasma ammonia value as high as 4,000?µM) with moderate increases in plasma levels of glutamine and alanine. Plasma concentrations of urea cycle intermediate amino acids are usually normal except for that of citrulline, which may be moderately elevated. The cause of the disorder is unknown. Urea cycle enzyme activities are normal. Treatment of hyperammonemia should be initiated promptly and continued vigorously. Recovery without sequelae is common, and hyperammonemia does not recur even with a normal protein diet.

Ornithine.

Ornithine is one of the intermediate metabolites of the urea cycle that is not incorporated into natural proteins. Rather, it is generated in the cytosol from arginine and must be transported into the mitochondria where it is used as a substrate for the enzyme OTC to form citrulline. Excess ornithine is catabolized by two enzymes, ornithine 5-aminotransferase, which is a mitochondrial enzyme and converts ornithine to a proline precursor, and ornithine decarboxylase, which resides in the cytosol and converts ornithine to putrescine (see Fig. 74–12). Two genetic disorders result in hyperornithinemia: gyrate atrophy of the retina and hyperammonemia-hyperornithinemia-homocitrullinemia syndrome.

GYRATE ATROPHY OF THE RETINA AND CHOROID.

This is a rare autosomal recessively inherited disorder caused by the deficiency of the enzyme ornithine 5-aminotransferase (see Fig. 74–12). About one third of the reported cases are from Finland. *Clinical manifestations* are limited to the eyes and include night blindness, myopia, loss of peripheral vision, and posterior subcapsular cataracts. These eye changes start between 5 and 10 yr of age and progress to complete blindness by the 4th decade of life. Atrophic lesions in the retina resemble cerebral gyri. These patients usually have normal intelligence. There is a 10- to 20-fold increase in plasma levels of ornithine (400 to 1400?µm). There is no occurrence of hyperammonemia and no increases in any other amino acids. In fact, plasma levels of glutamate, glutamine, lysine, creatine, and creatinine are moderately decreased. Some patients respond partially to high doses of pyridoxine (500–1,000?mg/24?hr). Arginine restricted diet in conjunction with supplemental lysine, proline, and creatine has been successful in reducing plasma ornithine concentration and has produced some clinical improvements. The gene for ornithine 5-aminotransferase is mapped to the long arm of chromosome 10q26. Several (at least 60) disease-causing mutations have been identified in different families.

HYPERAMMONEMIA-HYPERORNITHINEMIA-HOMOCITRULLINEMIA SYNDROME (HHH SYNDROME).

In this rare autosomal recessively inherited disorder the defect is in the transport system of ornithine from the cytosol into the mitochondria, which causes an accumulation of ornithine in the cytosol and a deficiency of ornithine inside the mitochondria. The former causes hyperornithinemia and the latter results in disruption of the urea cycle and hyperammonemia (see Fig. 74–12). Homocitrulline is presumably formed from the reaction

of mitochondrial carbamyl phosphate with lysine, which occurs because of the intramitochondrial deficiency of ornithine. *Clinical manifestations* of hyperammonemia may develop shortly after birth or may be delayed until adulthood. Acute episodes of hyperammonemia manifest as refusal to feed, vomiting, and lethargy; coma may occur during infancy. Progressive neurologic signs, such as lower limb weakness, increased deep tendon reflexes, spasticity, clonus, seizures, and varying degrees of psychomotor retardation may develop if the condition remains undiagnosed. No clinical ocular findings have been observed in these patients.

Laboratory findings reveal marked increases in plasma levels of ornithine and homocitrulline in addition to hyperammonemia. Restriction of protein intake improves hyperammonemia. Ornithine supplementation may produce clinical improvement in some patients. The gene for this disorder *(ORNT1)* is located on the long arm of chromosome 13q14.

74.12 Histidine

Iraj Rezvani

Histidine is an essential amino acid only during infancy. Its synthetic pathway in older children and adults is poorly understood. Histidine is degraded through the urocanic acid pathway to glutamic acid. Several genetic conditions involving the degradative pathway of histidine occur but none has any clinical consequence.

74.13 Lysine

Iraj Rezvani

The major pathway in the catabolism of lysine involves its condensation with a-ketoglutaric acid to form saccharopine. Saccharopine is then broken down to a-aminoadipic acid semialdehyde and glutaric acid. These first two steps are catalyzed by a-aminoadipic semialdehyde synthase, which has two activities, lysine-ketoglutarate reductase and saccharopine dehydrogenase (Fig. 74–14). In a minor pathway for lysine degradation, lysine is transaminated first and then condensed to the cyclic form, pipecolic acid. This is the major pathway for D-lysine in the body and for the L-lysine in the brain (see Fig. 74–14).

Hyperlysinemia, a-aminoadipic acidemia, and a-ketoadipic acidemia are three conditions that are due to inborn errors of metabolism of lysine. Individuals with these conditions are usually asymptomatic.

Glutaric Aciduria Type I.

Glutaric acid is an intermediate in the degradation of lysine (see Fig. 74–14), hydroxylysine, and tryptophan. Glutaric aciduria type I, a disorder caused by a deficiency of glutaryl CoA dehydrogenase, should be differentiated from glutaric aciduria type II, a distinct clinical and biochemical disorder caused by defects in the electron transport system (see Chapter 75.1).

CLINICAL MANIFESTATIONS.

Affected infants with glutaric aciduria type I may develop normally up to 2 yr of life. Macrocephaly is a common finding in these infants. Symptoms of hypotonia, loss of head control, choreoathetosis, seizures, generalized rigidity, opisthotonos, and dystonia may occur suddenly in a seemingly normal infant after a minor infection. Recovery from the first attack usually occurs slowly, but some residual neurologic abnormalities, especially dystonia and extrapyramidal movements, may persist. Additional acute episodes resembling the first one usually occur during an intercurrent infection. In other patients these signs and symptoms may develop gradually during the first few years of life and hypotonia and choreoathetosis may gradually progress into rigidity and dystonia. Acute episodes of metabolic decompensation with vomiting, ketosis, seizures, and coma also commonly occur in these patients after infection or other catabolic states. Death usually occurs in the first decade of life during one of these episodes. The intellectual abilities usually remain relatively normal in most patients.

LABORATORY FINDINGS.

During acute episodes, mild to moderate metabolic acidosis and ketosis may occur. Hypoglycemia, hyperammonemia, and elevations of serum transaminases have been seen in some patients. High concentrations of glutaric acid are usually found in urine, blood, and cerebrospinal fluid. 3-Hydroxyglutaric acid may also be present in the urine. This finding differentiated glutaric aciduria type I from type II. In glutaric aciduria type II, 2-hydroxyglutaric rather than 3-hydroxyglutaric acid is elevated. Plasma amino acid concentrations are usually within normal limits. Laboratory findings may be unremarkable between attacks. Severely affected children without glutaric aciduria also have been reported. In some of these patients glutaric acid is elevated only in the spinal fluid. Therefore, in any child with progressive dystonia and dyskinesia, activity of the enzyme glutaryl CoA dehydrogenase should be measured in leukocytes or cultured fibroblasts. CT scan and MRI of the brain reveal macrocephaly, dilated lateral ventricles, cortical atrophy, fibrosis, and atrophy of striatum (putamen and caudate).

Prenatal diagnosis has been accomplished by demonstrating increased concentrations of glutaric acid in amniotic fluid or by the enzyme deficiency in amniocytes or chorionic villi samples. The condition is inherited as an autosomal recessive trait. The prevalence is not known. The condition is more prevalent in Sweden and among the Old Order Amish population in the United States.

TREATMENT.

A low-protein diet (especially a diet restricted in lysine and tryptophan) and high doses (200–300?mg/24?hr) of riboflavin (the coenzyme for glutaryl CoA dehydrogenase) and carnitine (50–100?mg/kg/24?hr) have resulted in a dramatic decrease in the levels of glutaric acid in body fluids, but the clinical effect has been variable. The addition of a GABA analogue (baclofen) and valproic acid to the therapeutic regimen has produced clinical improvement in some affected children.

The gene is located on the short arm of chromosome 19p13.2.

Lysinuric Protein Intolerance (Familial Protein Intolerance).

This rare autosomal recessive disorder is due to a defect in the transport of cationic amino acids, lysine, ornithine, and arginine in both kidneys and intestine. Unlike patients with cystinuria, urinary excretion of cystine is not increased in these patients. About half of the reported cases have been from Finland, where the prevalence has been estimated to be 1 in 60,000.

Clinical manifestations consist of refusal to feed, nausea, aversion to protein, vomiting, and mild diarrhea, which may result in failure to thrive, wasting, and hypotonia. Breast-fed infants usually remain asymptomatic until shortly after weaning. This may be due to the low protein content of breast milk. Episodes of hyperammonemia may occur after ingestion of a high-protein diet. Mild to moderate hepatosplenomegaly, osteoporosis, sparse brittle hair, thin extremities with moderate centripetal adiposity, and growth retardation are common physical findings. Mental development is usually normal, but moderate mental retardation has been observed in 20% of patients. Interstitial pneumonitis manifesting with fever, fatigue, cough, and dyspnea occur as an acute episode or as a chronic progressive process. Some patients have remained undiagnosed until the appearance of pulmonary manifestations. Radiographic evidence of pulmonary fibrosis has been observed in up to 65% of patients without clinical manifestations of pulmonary involvement. Acute attacks of pulmonary proteinosis have occurred in older patients. Renal involvement resembling glomerulonephritis has been observed as part of a multisystem disease that may develop as a terminal event.

Figure 74.13-14 Pathways in the metabolism of lysine. **Enzymes:** (1) lysine ketoglutarate reductase; (2) saccharopine dehydrogenase; (3) a-aminoadipic acid transferase; (4) a-ketoadipic acid dehydrogenase; (5) glutaryl CoA dehydrogenase; (6) a-aminoadipic semialdehyde oxidase.

Laboratory findings may reveal hyperammonemia and an elevated concentration of urinary orotic acid, which develop only after protein feeding. Fasting blood ammonia and urinary orotic acid excretion are usually normal. Plasma concentrations of lysine, arginine, and ornithine are usually mildly decreased, but urinary levels of these amino acids, especially lysine, are greatly increased. The exact mechanism producing hyperammonemia is not clear. All enzymes of the urea cycle are normal. Hyperammonemia is thought to be related to a disturbance of the urea cycle secondary to a deficiency of arginine and ornithine. However, in patients with cystinuria who also have defects in the transport of lysine, arginine, and ornithine in both intestine and kidneys, hyperammonemia is not observed. Plasma concentrations of alanine, glutamine, serine, glycine, proline, and citrulline are usually increased. These abnormalities may be secondary to hyperammonemia and are not specific to this disorder.

Mild anemia and increased serum levels of ferritin, lactic dehydrogenase (LDH), and thyroxine-binding globulin also have been observed in these patients. This condition should be differentiated from hyperammonemia caused by defects in the urea cycle (see Chapter 74.11), especially in heterozygous females with OTC deficiency. Increased urinary excretion of lysine, ornithine, and arginine and elevated blood levels of citrulline are not seen in patients with OTC deficiency.

The transport defect in this condition resides in the basolateral (antiluminal) membrane of enterocytes and renal tubular epithelia. This explains the observation that cationic amino acids are unable to cross these cells even when administered as dipeptides. Lysine in the form of dipeptide crosses the luminal membrane of the enterocytes but hydrolyzes to free lysine molecules in the cytoplasm. Free lysine, unable to cross the basolateral membrane of the cells, is diffused back into the lumen.

Pregnancies in affected mothers have been complicated by anemia, thrombocytopenia, toxemia, and bleeding, but offspring have been normal.

Treatment with a low-protein diet (1.0–1.5?g/kg/24?hr) supplemented with citrulline (200?mg/kg/24?hr) has produced biochemical and clinical improvements. Episodes

of hyperammonemia should be treated promptly (see Chapter 74.11). Supplementation with lysine is not useful because it is poorly absorbed and tends to produce diarrhea and abdominal pain. Treatment with high doses of prednisone and bronchoalveolar lavage has been effective in the management of acute pulmonary complications.

74.14 Aspartic Acid (Canavan Disease)

Reuben K. Matalon

N-Acetylaspartic acid, a derivative of aspartic acid, is synthesized in the brain, where it is found in high concentrations, similar to glutamic acid. Its function is unknown, but excessive amounts of *N*-acetylaspartic acid in urine and a deficiency of the enzyme aspartoacylase that cleaves the *N*-acetyl group from *N*-acetylaspartic acid causes Canavan disease.

Canavan Disease.

Canavan disease, an autosomal recessive disorder characterized by spongy degeneration of the white matter of the brain, leads to a severe form of leukodystrophy. It is more prevalent in individuals of Ashkenazi Jewish descent than in other ethnic groups.

ETIOLOGY AND PATHOLOGY.

The deficiency of the enzyme aspartoacylase leads to the accumulation of *N*-acetylaspartic acid in the brain, especially in white matter with massive urinary excretion of this compound. Excessive amounts of

Figure 74.14-15 Axial T-weighted MRI of a 2-yr-old patient with Canavan disease. Extensive thickening of the white matter is seen.

N-acetylaspartic acid are also present in the blood and cerebrospinal fluid. There is striking vacuolization and astrocytic swelling in white matter. Electron microscopy reveals distorted mitochondria. As the disease progresses, the ventricles enlarge from cerebral atrophy.

CLINICAL MANIFESTATIONS.

The severity of Canavan disease covers a wide spectrum. Infants usually appear normal at birth and may not manifest symptoms until 3–6 mo of age, when they develop progressive macrocephaly, severe hypotonia, and persistent head lag. As the infant grows older, delayed milestones become evident. These children become

hyperreflexic and hypertonic; joint stiffness may be encountered because of disuse. Seizures and optic atrophy develop with time. Feeding difficulties, poor weight gain, and gastroesophageal reflux may occur in the 1st yr of life; swallowing deteriorates during the 2nd and 3rd yr of life, and nasogastric feeding or permanent gastrostomy may be required. Most patients die in the first decade of life; however, with improved nursing care they may survive through the second decade.

DIAGNOSIS.

CT scans and MRI reveal diffuse white matter degeneration, primarily in the cerebral hemispheres, with less involvement in the cerebellum and brain stem (Fig. 74–15). Repeated evaluations may be required. Magnetic resonance spectroscopy (MRS) performed at the time MRI is done may show a high peak of *N*-acetylaspartic acid suggesting Canavan disease. The differential diagnosis of Canavan disease should include *Alexander disease*, which is another leukodystrophy with macrocephaly. Progression is usually slow in Alexander disease; hypotonia is not as pronounced as in Canavan disease. Brain biopsy shows spongy degeneration of the myelin fibers, astrocytic swelling, and elongated mitochondria. Definitive diagnosis is established by finding elevated amounts of *N*-acetylaspartic acid in the urine or blood with a deficiency of aspartoacylase in cultured skin fibroblasts. The biochemical method is the preferred choice for diagnosis. Levels of *N*-acetylaspartic acid in normal urine are only trace amounts (24 ± 16?µmol/mmol creatinine), whereas in patients with Canavan disease they are in the range of 1,440 ± 873?µmol/mmol creatinine. High levels of *N*-acetylaspartic acid in plasma, cerebrospinal fluid, and brain tissue can also be detected. The activity of aspartoacylase in the fibroblasts of obligate carriers is about half or less of the activity found in normal individuals.

The gene for aspartoacylase has been cloned, and mutations leading to Canavan disease have been identified. There are two mutations predominant in the Ashkenazi Jewish population. The first is an amino acid substitution (E285A) in which glutamic acid is substituted to alanine. This mutation is the most frequent and encompasses 83% of 100 mutant alleles examined in Ashkenazi Jewish patients. The second common mutation is a change from tyrosine to a nonsense mutation, leading to a stop in the coding sequence (Y231X). This mutation accounts for 13% of the 100 mutant alleles. In the non-Jewish population more diverse mutations have been observed; the two common mutations in Jewish people are rare. A different mutation (A305E), substitution of alanine for glutamic acid, accounts for 40% of 62 mutant alleles in non-Jewish patients. It is important to obtain a molecular diagnosis because this will lead to accurate counseling and prenatal diagnosis for the family. If the mutations are not known, prenatal diagnosis relies on the level of *N*-acetylaspartic acid in the amniotic fluid. In Ashkenazi Jewish patients the carrier frequency may be as high as 1 in 36, which is close to that of Tay-Sachs disease. Ashkenazi Jewish individuals may need to be screened for Canavan disease.

TREATMENT AND PREVENTION.

No specific treatment is available. Feeding problems and seizures should be treated on an individual basis. Genetic counseling, carrier testing, and prenatal diagnosis are available. Injection of liposomes with the human aspartoacylase gene was introduced to the ventricles of two children with Canavan disease. The results of this gene therapy have not been encouraging.

Chapter 75 - Defects in Metabolism of Lipids

75.1 Disorders of Mitochondrial Fatty Acid Oxidation

Charles P. Venditti
Charles A. Stanley

Mitochondrial oxidation of fatty acids is an essential energy-producing pathway. It becomes especially important during prolonged periods of starvation when the body switches from using predominantly carbohydrates to predominantly fat as its major fuel. Fatty acids are also important fuels for exercising skeletal muscle and are the preferred substrate for the heart. In these tissues, fatty acids are completely oxidized to carbon dioxide and water. The end products of hepatic fatty acid oxidation are the ketones ß-hydroxybutyrate and acetoacetate that cannot be oxidized by the liver but serve as important fuels in peripheral tissues, particularly the brain.

Genetic defects occur in nearly all the steps in the fatty acid oxidation path; all are recessively inherited. *Clinical manifestations* are similar among the disorders. The most common presentation is an acute attack of life-threatening coma and hypoglycemia induced by a period of fasting. Other manifestations frequently may include chronic cardiomyopathy and muscle weakness or, more rarely, acute rhabdomyolysis. These defects can be asymptomatic except during fasting stress and may be misdiagnosed as Reye syndrome or sudden infant death syndrome. Fatty acid oxidation disorders are easily overlooked because the only specific clue to the diagnosis may be the finding of inappropriately low concentrations of urinary ketones in an infant who has hypoglycemia. Genetic defects in ketone utilization may be overlooked because ketosis is an expected finding with fasting hypoglycemia. In some circumstances, clinical manifestations appear to arise from toxic effects of fatty acid metabolites rather than simply inadequate energy production. These include disorders (LCHAD, CPT1, SCAD, see later) in which the presence of an affected fetus has been suggested to increase the risk of a life-threatening illness in the heterozygote mother mimicking acute fatty liver of pregnancy or preeclampsia with HELLP syndrome. Malformations of the brain and kidneys have been described in severe ETF-ETF-DH and CPT-2 deficiency that might reflect in utero toxicity of fatty acid metabolites. Newborn metabolic screening programs that utilize tandem mass spectrometry (MS/MS) can readily detect the abnormal acylcarnitines seen in many of these disorders and permit the presymptomatic diagnosis. Screening programs have shown that fatty acid oxidation disorders are among the most common inborn errors of metabolism.

Figures 75–1 and 75–2 outline the steps involved in mitochondrial oxidation of a typical long-chain fatty acid. In the *carnitine cycle*, fatty acids are carried across the

barrier of the inner mitochondrial membrane linked to carnitine. Within the mitochondrial matrix, successive turns of the four-step ß-oxidation cycle convert the fatty acid to acetyl-coenzyme A (CoA) units. Two to four chain-length specific isoenzymes are needed for each of these ß-oxidation steps to accommodate the different-sized fatty acids. The *electron transfer pathway* carries electrons generated in the first ß-oxidation step to the electron transport chain for adenosine triphosphate (ATP) production. Most of the acetyl-CoA generated from hepatic ß-oxidation flows through the *ketone synthesis pathway* to ß-hydroxybutyrate and acetoacetate.

DEFECTS IN THE ß-OXIDATION CYCLE

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common of the fatty acid oxidation disorders. The disorder shows a strong founder effect: most patients have a northwestern European ancestry, and 85–90% are homozygous for a single common missense mutation: an A?G transition at cDNA position 985.

Clinical Manifestations.

Affected patients usually present in the first 2–3 yr of life with episodes of acute illness triggered by prolonged fasting lasting more than 12–16?hr. Signs and symptoms include vomiting and lethargy, which rapidly progress to coma or seizures and cardiorespiratory collapse. The liver may be slightly enlarged with fat deposition. Attacks are rare until the infant is beyond the first few months of life. Affected older infants are at higher risk of illness as they begin to fast through the night or are exposed to fasting stress during an intercurrent childhood illness. Presentation in the first days of life has been reported in newborns who were fasted inadvertently before successful breast-feeding. Diagnosis of MCAD has occasionally been documented in previously healthy teenage and adult individuals, indicating that even patients who are “asymptomatic” are at risk for metabolic decompensation if exposed to sufficient periods of fasting.

Laboratory Findings.

During acute episodes, hypoglycemia is usually present. Plasma and urinary ketone concentrations are inappropriately low (hypoketotic hypoglycemia). Because of the absence of ketones, there is little or no acidemia. Tests of liver function are abnormal, with elevations of transaminases, urate, urea, ammonia, and prolonged thrombin and partial thromboplastin times. Liver biopsy results at times of acute illness show increased triglyceride deposition in either a microvesicular or macrovesicular pattern. During fasting stress or at times of acute illness, urinary organic acid profiles by gas chromatography/mass spectrometry show low concentrations of ketones and elevated levels of medium-chain dicarboxylic acids that derive from microsomal and peroxisomal omega oxidation of fatty acids. Plasma and tissue concentrations of total carnitine are reduced to 25–50% of normal, and the fraction of total esterified carnitine is increased. This pattern of *secondary carnitine deficiency* is seen in almost all the fatty acid oxidation defects and reflects competition between increased acylcarnitine levels and free carnitine transport at the plasma membrane. Significant exceptions to this rule are the carnitine transporter, CPT-1, and HMG-CoA synthase deficiencies.

Diagnosis can be made by demonstrating abnormal metabolites in plasma (octanoylcarnitine) or urine (glycine conjugates of hexanoate and phenylpropionate) or by showing deficiency of the enzyme in cultured fibroblasts. Mass spectrometry newborn metabolic screening programs can diagnose presymptomatic infants based on the detection of octanoylcarnitine in filter paper blood spots. In some cases, the diagnosis can be confirmed by finding the common A985G mutation. A rare mutation G583A is associated with severe MCAD deficiency, hypoglycemia, and sudden neonatal death. A second, common

---

Figure 75.1-1 Mitochondrial fatty acid oxidation. Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long-chain fatty acid, is transported across the plasma membrane and can be activated to form a long chain (LC) fatty acyl-CoA. It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into a long-chain fatty acyl CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo ß-oxidation. Very long chain acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of (C16-10) 2,3 enoyl-CoA. Trifunctional protein (TFP) contains the activities of enoyl-CoA hydratase (hydratase), 3-OH-hydroxyacyl CoA dehydrogenase (3-OH-ACD), and ß-ketothiolase (thiolase). Acetyl CoA, FADH, and NADH are produced. Medium- and short-chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short-chain acyl-CoA dehydrogenase (SCAD), and short-chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron-transfer flavoprotein (ETF) and the electron-transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. Acetyl-CoA can be converted into hydroxymethylglutaryl-CoA (HMG-CoA) by ß-hydroxy-ß-methylglutaryl-CoA synthase (HMG-CoA synthase) and then the ketone body acetoacetate by the action of ß-hydroxy-ß-methylglutaryl-CoA lyase (HMG-CoA lyase).

mutation, T199C, has been detected in infants with increased octanoylcarnitine in newborn screening tests. This allele has not been seen in symptomatic MCAD patients, however, and may represent a mild mutation that does not cause disease.

Treatment.

Acute illnesses should be promptly treated with intravenous fluids containing 10% dextrose to suppress lipolysis as rapidly as possible. Chronic therapy consists of avoiding fasting. This usually requires simply adjusting the diet to ensure that overnight fasting periods are limited to less than 10–12?hr. Restricting dietary fat or treatment with carnitine is controversial.

Prognosis.

Up to 25% of patients may die during their first attack of illness. Some patients may have permanent brain injury during an attack. The prognosis for survivors is good because muscle weakness or cardiomyopathy does not occur in MCAD deficiency. Fasting tolerance improves with age, and the risk of illness decreases. As many as

50% of affected patients never have an episode; therefore, testing of siblings of affected patients is important to detect asymptomatic family members.

Long-Chain/Very Long Chain Acyl-CoA Dehydrogenase Deficiency

Long-chain/very long chain acyl-CoA dehydrogenase (LCAD/ VLCAD) deficiency was originally termed *LCAD deficiency* before the existence of an additional VLCAD enzyme specific for longer chain fatty acids was known. All patients previously diagnosed as having LCAD deficiency have VLCAD enzyme deficiency. No patients with isolated LCAD deficiency have been described.

Patients are usually more severely affected than those with MCAD deficiency, presenting earlier in infancy and having more

Figure 75.1-2 Pathway of mitochondrial oxidation of palmitate, a typical 16-carbon long-chain fatty acid. Enzyme steps include carnitine palmitoyltransferase (CPT) 1 and 2, carnitine/acylcarnitine translocase (TRANS), electron transfer flavoprotein (ETF), ETF-dehydrogenase (ETF-DH), acyl-CoA dehydrogenase (ACD), enoyl-CoA hydratase (hydratase), 3-hydroxy-acyl-CoA dehydrogenase (3-OH-ACD), ß-ketothiolase (thiolase), ß-hydroxy-B-methylglutaryl-CoA (HMG-CoA) synthase, and lyase.

chronic problems with muscle weakness or episodes of muscle pain and rhabdomyolysis. Cardiomyopathy may be present during acute attacks associated with fasting. The left ventricle may be hypertrophic or dilated and show poor contractility on echocardiography. Sudden unexpected death has occurred in several patients, but most who survived the initial episode showed improvement, including normalization of cardiac function. Other physical and routine laboratory features are similar to those of MCAD deficiency, including secondary carnitine deficiency. The urinary organic acid profile shows a hypoketotic dicarboxylic aciduria. Increased levels of $C_{12–14}$ dicarboxylic acids may be noted in the urine. *Diagnosis* may be suggested by the demonstration of elevated plasma $C_{14:1}$ fatty acid or acylcarnitine, but the specific diagnosis requires assay of enzyme activities of both LCAD and VLCAD in cultured fibroblasts. The VLCAD gene has been cloned and mutations have been characterized. Inheritance is autosomal recessive. *Treatment* is avoidance of fasts for more than 10–12?hr. Continuous intragastric feeding is useful in some patients.

Short-Chain Acyl-CoA Dehydrogenase Deficiency

A small number of biochemically-verified SCAD patients have been described. Affected individuals do not present with hypoketotic hypoglycemia. Skeletal myopathy seems to predominate in most patients, but a consistent clinical phenotype has not been identified. Some patients have severe metabolic acidosis. Neurologic signs are present in most patients, although mildly affected individuals may be asymptomatic and display only minimal elevations of ethylmalonic acid in the urine. Some of these features suggest a toxicity syndrome, perhaps owing to accumulation of short-chain fatty acid metabolites. One reported patient had normal ketogenesis, implying that there is no impairment of longer chain fatty acid oxidation. Urinary organic acid profile usually shows elevations of short-chain fatty acid metabolites, particularly ethylmalonic acid. Secondary carnitine deficiency is present, and butyrylcarnitine levels may be elevated in the blood.

Diagnosis based solely on the specific metabolite profile in blood and urine may be difficult because some patients do not consistently excrete characteristic metabolites. Confirmation of the diagnosis by enzyme assay in cultured cells and DNA-based testing may be helpful. Mutations have been identified in the SCAD gene in affected patients, and two common SCAD mutations have been associated with ethylmalonic aciduria. *Treatment* is limitation of fasting stress and dietary fat.

Long-Chain 3-Hydroxyacyl-CoA Dehydrogenase Deficiency

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency is the second most common of the fatty acid oxidation disorders. The LCHAD enzyme is part of a trifunctional protein (TFP), which also contains two other steps in ß-oxidation, long-chain enoyl-CoA hydratase and ß-keto-thiolase. It is a hetero-octameric protein composed of a and ß chains that derive from distinct genes. In some patients, only the LCHAD activity of the TFP is affected, whereas others have deficiencies of all three activities. *Clinical manifestations* include attacks of acute hypoketotic hypoglycemia similar to MCAD deficiency; patients often show evidence of more severe disease, including cardiomyopathy, muscle weakness, and abnormal liver function. Toxic effects of fatty acid metabolites may produce retinopathy, progressive liver failure, peripheral neuropathy, and rhabdomyolysis. A life-threatening illness, acute fatty liver of pregnancy (and perhaps HELLP syndrome), has been observed in heterozygotic mothers carrying fetuses affected with LCHAD deficiency. Urinary organic acid profile in patients may show increases in levels of 3-hydroxydicarboxylic acids. Secondary carnitine deficiency is common; plasma 3-hydroxydicarboxylic acid esters of carnitine and 3-hydroxy long-chain fatty acids are

---

increased in blood. A common mutation in the a subunit, E474Q, is seen in more than 80% of LCHAD patients. This mutation in the fetus is significantly associated with **acute fatty liver of pregnancy**.

Treatment is similar to that for MCAD or LCAD/VLCAD deficiency by avoiding a fasting stress. Dietary restriction of long-chain fatty acids with supplementation of medium-chain triglyceride oil may improve hypotonia, hepatomegaly, cardiomyopathy, and lactic acidosis in some patients but does not appear to alter the progressive peripheral neuropathy, pigmentary retinopathy, or myoglobinuria. Liver transplantation does not ameliorate the metabolic abnormalities.

Short-Chain 3-Hydroxyacyl-CoA Dehydrogenase Deficiency

Very few patients with this inborn error have been described. One patient had attacks of fasting hypoglycemia and myoglobinuria associated with deficiency of short-chain 3-hydroxyacyl-CoA dehydrogenase in muscle but not in cultured fibroblasts. The patient died in adolescence with cardiomyopathy and arrhythmias.

Another report described two children with recurrent episodes of fasting ketotic hypoglycemia. SCHAD-enzyme activity was reduced in fibroblast mitochondria. Two patients with proven mutations of SCHAD have been reported. One presented with fulminant hepatic failure at age 3 yr and had mutations in the highly conserved NAD binding domain of the SCHAD gene. The other was a 4-mo-old girl with a homozygous missense SCHAD mutation who presented with hypoketotic hypoglycemia but also had evidence of hyperinsulinism and, in contrast to patients with other forms of fatty acid oxidation disorders, required specific therapy for the latter to avoid hypoglycemia.

DEFECTS IN THE CARNITINE CYCLE

Plasma Membrane Carnitine Transport Defect (Primary Carnitine Deficiency)

Primary carnitine deficiency is the only genetic defect in which carnitine deficiency is the cause, rather than the consequence, of impaired fatty acid oxidation. The most common presentation is progressive cardiomyopathy with or without skeletal muscle weakness beginning at 2–4 yr of age. A smaller number of patients may present with fasting hypoketotic hypoglycemia during the 1st yr of life before the cardiomyopathy becomes symptomatic. The underlying defect involves the plasma membrane sodium gradient–dependent carnitine transporter that is present in heart, muscle, and kidney. This transporter is responsible both for maintaining intracellular carnitine concentrations 20- to 50-fold higher than plasma concentrations and for renal conservation of carnitine.

Diagnosis of the carnitine transporter defect is aided by the fact that patients have extremely reduced carnitine levels in plasma and muscle (1–2% of normal). Heterozygote parents have plasma carnitine levels approximately 50% of normal. Fasting ketogenesis may be normal because liver carnitine transport is normal, but it may be impaired if dietary carnitine intake is interrupted. The fasting urinary organic acid profile may show a hypoketotic dicarboxylicaciduria pattern if hepatic fatty acid oxidation is impaired, but it is otherwise unremarkable. The defect in carnitine transport can be demonstrated clinically by severe reduction in renal carnitine threshold or in vitro by assay of carnitine uptake using cultured fibroblasts or lymphoblasts. Mutations in the organic cation/carnitine transporter OCTN2 underlie this disorder. *Treatment* of this disorder with pharmacologic doses of oral carnitine is highly effective in correcting the cardiomyopathy and muscle weakness as well as any impairment in fasting ketogenesis. Muscle total carnitine concentrations remain less than 5% of normal on treatment.

Carnitine Palmitoyltransferase-1 Deficiency

Several infants and children have been described with a deficiency of the liver isozyme of carnitine palmitoyltransferase-1. *Clinical manifestations* include fasting hypoketotic hypoglycemia, occasionally with markedly abnormal liver function tests. The heart and skeletal muscle are not involved because the muscle isozyme is unaffected. Fasting urinary organic acid profile shows a hypoketotic dicarboxylicaciduria but no specific abnormalities. *Diagnosis* is aided by the observation that this is the only fatty acid oxidation disorder in which plasma total carnitine levels are elevated to 150–200% of normal. This may be explained by the fact that the inhibitory effects of long-chain acylcarnitines on the renal tubular carnitine transporter are absent in carnitine palmitoyltransferase-1 deficiency. The enzyme defect can be demonstrated in cultured fibroblasts or lymphoblasts. One patient with elevated free carnitine on a newborn blood spot was subsequently found to be deficient in carnitine palmitoyltransferase-1, indicating that this disorder may be readily detectable by tandom mass spectroscopy neonatal metabolic screening. Carnitine palmitoyltransferase-1 deficiency in the fetus has been associated with acute fatty liver of pregnancy in the mother. *Treatment* with diet to avoid fasting is similar to that for MCAD deficiency.

Carnitine-Acylcarnitine Translocase Deficiency

This defect of the inner mitochondrial membrane carrier protein for fatty acylcarnitines blocks the entry of long-chain fatty acids into the mitochondria for oxidation. The clinical phenotype of this disorder is characterized by a severe and generalized impairment of fatty acid oxidation. Most newborn patients present with attacks of fasting-induced hypoglycemia and cardiorespiratory collapse. All symptomatic newborns have had evidence of cardiomyopathy and muscle weakness. Several patients with a partial translocase deficiency and milder disease without cardiac involvement have also been identified. No distinctive urinary or plasma organic acids are noted, although unusually increased levels of long-chain acylcarnitines are reported. A secondary deficiency of carnitine can occur. *Diagnosis* can be made using cultured fibroblasts or lymphoblasts. The human gene has been cloned, and mutations have been identified in affected patients. *Treatment* is similar to that of other fatty acid oxidation disorders.

Carnitine Palmitoyltransferase-2 Deficiency

Three forms of carnitine palmitoyltransferase-2 deficiency have been described. The antenatal presentation of this disorder is associated with a profound enzyme deficiency, and neonatal death and has been reported in several newborns with dysplastic kidneys, cerebral malformations, and mild facial anomalies. A severe deficiency of enzyme activity is associated with an infantile-onset form. This form shares all the clinical and laboratory features of the carnitine-acylcarnitine translocase deficiency described earlier. A milder defect is associated with an adult presentation of episodic rhabdomyolysis. The first episode usually does not occur until late childhood or early adulthood. Attacks may be precipitated by prolonged exercise. There is aching muscle pain and myoglobinuria that may be severe enough to cause renal failure. Serum levels of creatine kinase are elevated to 5,000–10,000?U/L. Fasting hypoglycemia has not been described, but fasting may contribute to attacks of myoglobinuria; ketogenesis may be impaired. Muscle biopsy shows increased deposition of neutral fat. Diagnosis can be made by demonstrating deficient enzyme activity in muscle or other tissues and in cultured fibroblasts. Mutation analysis can also be performed.

DEFECTS IN ELECTRON TRANSFER PATHWAY

Electron Transfer Flavoprotein and Electron Transfer Flavoprotein Dehydrogenase (ETF-DH) Deficiencies (Glutaric Aciduria Type 2, Multiple Acyl-CoA Dehydrogenation Deficiencies)

Electron transfer flavoprotein (ETF) and electron transfer flavoprotein dehydrogenase (ETF-DH) function to transfer electrons into the mitochondrial electron transport chain from dehydrogenation reactions catalyzed by MCAD, SCAD, LCAD, and VLCAD, as well as glutaryl-CoA dehydrogenase and two enzymes involved in branch-chain amino acid oxidation, isovaleryl-CoA dehydrogenase and branch-chain acyl-CoA dehydrogenase. Deficiencies of ETF or ETF-DH produce illness that combines the features of impaired fatty acid oxidation and impaired oxidation of several of the amino acids, such as leucine and lysine. Complete deficiencies of either enzyme are associated with severe illness in the newborn period, characterized by acidosis, hypoglycemia, coma, hypotonia, and cardiomyopathy. Some affected neonates have had facial dysmorphia and polycystic kidneys, which suggests that toxic effects of accumulated metabolites may occur in utero. *Diagnosis* can be made from the urinary organic acid profile, which shows abnormalities corresponding to blocks in oxidation of fatty acids (ethylmalonate and dicarboxylic acids), lysine (glutarate), and branched-chain amino acids (isovaleryl-, isobutyryl-, and a-methylbutyryl-glycine). Most severely affected infants do not survive the neonatal period.

Partial deficiencies of ETF and ETF-DH produce a disorder that may mimic MCAD deficiency or other milder fatty acid oxidation defects. These patients have attacks of fasting hypoketotic coma. The urinary organic acid profile reveals primarily elevations of dicarboxylic acids and ethylmalonate, derived from short-chain fatty acid intermediates. Secondary carnitine deficiency is present. Some patients with mild forms of ETF/ETF-DH deficiency benefit from *treatment* with high doses of riboflavin, the cofactor for these two enzymes as well as for the acyl-CoA dehydrogenases.

DEFECTS IN KETONE SYNTHESIS PATHWAY

ß-Hydroxy-ß-Methyl Glutaryl-CoA Synthase Deficiency

ß-Hydroxy-ß-methyl glutaryl-CoA synthase is the rate-limiting step in conversion of acetyl-CoA derived from fatty acid ß-oxidation in the liver to ketones. Three patients with this defect have been identified. The presentation is one of fasting hypoketotic hypoglycemia without evidence of impaired cardiac or skeletal muscle function. Urinary organic acid profile showed only a hypoketotic dicarboxylic aciduria. Plasma and tissue carnitine levels were normal, in contrast to all the other disorders of fatty acid oxidation. A separate synthase enzyme, present in cytosol for cholesterol biosynthesis, is not affected. The ß-hydroxy-ß-methyl glutaryl-CoA synthase defect is expressed only in the liver and cannot be demonstrated in cultured fibroblasts. The gene has been cloned, and mutations in the affected patients have been characterized. Avoiding fasting is usually a successful treatment.

ß-Hydroxy-ß-Methyl Glutaryl-CoA Lyase Deficiency

See Chapter 74.6 .

DEFECTS IN KETONE UTILIZATION

The ketones ß-hydroxybutyrate and acetoacetate are the end products of hepatic fatty acid oxidation and are important as metabolic fuels for the brain during fasting. Two defects in utilization of ketones in brain and other peripheral tissues present as episodes of “hyperketotic” with or without hypoglycemia.

Succinyl-CoA Acetoacetyl-CoA Transferase Deficiency

Several patients with succinyl-CoA acetoacetyl-CoA transferase (SCOT) deficiency have been reported. One presented with recurrent episodes of severe ketoacidosis beginning in the newborn period and died at 6 mo of age. Treatment of episodes required infusion of glucose and large amounts of bicarbonate for 3–4 days. All patients exhibit inappropriate hyperketonemia. The enzyme is responsible for activating acetoacetate in peripheral tissues using succinyl-CoA as a donor to form acetoacetyl-CoA. Deficient activity can be demonstrated in brain, muscle, and fibroblasts from affected patients. The gene has been cloned, and mutations have been characterized.

ß-Ketothiolase Deficiency

See Chapter 74.6 .

75.2 Disorders of Very Long Chain Fatty Acids

Hugo W. Moser

PEROXISOMAL DISORDERS

The peroxisomal diseases are genetically determined disorders caused by either the failure to form or maintain the peroxisome or a defect in the function of a single enzyme that is normally located in this organelle. These disorders cause serious disability in childhood and occur more frequently and present a wider range of phenotype than has been recognized in the past.

Etiology.

Peroxisomal disorders are subdivided into two major categories (Box 75–1).

Box 75.2-1. Classification of Peroxisomal Disorders

A: DISORDERS OF PEROXISOME IMPORT

A1: Zellweger syndrome

A2: Neonatal adrenoleukodystrophy

A3: Infantile Refsum disease

A4: Rhizomelic chondrodysplasia punctata

B: DEFECTS OF SINGLE PEROXISOMAL ENZYME

B1: X-linked adrenoleukodystrophy

B2: Acyl-CoA oxidase deficiency

B3: Bifunctional enzyme deficiency

B4: Peroxisomal thiolase deficiency

B5: Classic Refsum disease

B6: 2-Methylacyl-CoA racemase deficiency

B7: DHAP acyltransferase deficiency

B8: Alkyl-DHAP synthase deficiency

B9: Mevalonic aciduria

B10: Glutaric aciduria type III

B11: Hyperoxaluria type I

B12: Acatalasemia

In category A, the peroxisomal biogenesis disorders (PBD), the basic defect is the failure to import one or more proteins into the organelle. In the second category, defects affect a single peroxisomal protein. The peroxisome is present in all cells except mature erythrocytes and is a subcellular organelle surrounded by a single membrane; more than 50 peroxisomal enzymes have been identified. Some enzymes are involved in the production and decomposition of hydrogen peroxide; others are concerned with lipid and amino acid metabolism. Most peroxisomal enzymes are first synthesized in their mature form on free polyribosomes and enter the cytoplasm. Proteins that are destined for the peroxisome contain specific peroxisome targeting sequences (PTS). Most peroxisomal matrix proteins contain PTS1, a 3-amino acid sequence at the carboxyl terminus. PTS2 is an amino-terminal sequence that is critical for the import of enzymes involved in plasmalogen and branched-chain fatty acid metabolism. Import of proteins involves a complex series of reactions that involves at least 23 distinct proteins. These proteins are referred to as peroxins encoded by *PEX* genes. Table 75–1 summarizes the *PEX* genes that are defective in human disease states.

From Moser HW: Genotype-phenotype correlations in disorders of peroxisome biogenesis. Mol Genet Metab 1999; 68:316.

Epidemiology.

Except for X-linked adrenoleukodystrophy (X-ALD), all the peroxisomal disorders in Box 75–1 are autosomal recessive traits. X-ALD is the most common peroxisomal disorder, with an estimated incidence of 1:17,000. The combined incidence of the other peroxisomal disorders is estimated to be 1:50,000.

Pathology.

Absence or reduction in the number of peroxisomes is pathognomonic for disorders of peroxisome biogenesis. In most disorders there are membranous sacs that contain peroxisomal integral membrane proteins, which lack the normal complement of matrix proteins; these are peroxisome “ghosts.” Pathologic changes are observed in many organs and include profound and characteristic defects in neuronal migration; micronodular cirrhosis of the liver; renal cysts; chondrodysplasia punctata; corneal clouding, congenital cataracts, glaucoma, and retinopathy; congenital heart disease; and dysmorphic features.

Pathogenesis.

It is likely that all pathologic changes are secondary to the peroxisome defect. Multiple peroxisomal enzymes fail to function in the PBD (Box 75–2). The enzymes that are diminished or absent are synthesized but are degraded abnormally fast because they may be unprotected outside of the peroxisome. It is not clear how defective peroxisome functions lead to the widespread pathologic manifestations.

The PBD are associated with genetically determined import defects. The PBD have been subdivided into 11 complementation groups. The molecular defects have been defined in 10 of these groups (see Table 75–1). The pattern and severity of pathologic features vary with the nature of the import defects and the degree to which import is impaired. These gene defects lead to disorders that were named before their relationship to the peroxisome was recognized, namely, Zellweger syndrome (ZS), neonatal adrenoleukodystrophy (NALD), infantile Refsum disease (IRD), and rhizomelic chondrodysplasia punctata (RCDP). The first three disorders are now considered to form a clinical continuum, with ZS the most severe, IRD the least severe, and NALD intermediate. They can be caused by 10 different gene defects, which involve mainly the import of proteins that contain the PTS1 targeting signal; the gene defects cannot be

Box 75.2-2. Abnormal Laboratory Findings Common to Disorders of Peroxisome Biogenesis

Peroxisomes absent or reduced in number

Catalase in cytosol

Deficient synthesis and reduced tissue levels of plasmalogens

Defective oxidation and abnormal accumulation of very long chain fatty acids

Deficient oxidation and age-dependent accumulation of phytanic acid

Defects in certain steps of bile acid formation and accumulation of bile acid intermediates

Defects in oxidation and accumulation of L-pipecolic acid

Increased urinary excretion of dicarboxylic acids

distinguished on the basis of clinical features. The clinical severity varies with the degree to which protein import is impaired. Mutations that abolish import completely often are associated with the ZS phenotype, whereas a missense mutation, in which some degree of import function is retained, leads to the somewhat milder phenotypes. A defect in *PEX7*, which involves the import of proteins that utilize PTS2, is associated with rhizomelic chondrodysplasia punctata (RCDP). *PEX7* defects that leave import partially intact are associated with milder phenotypes, some of which resemble classic Refsum disease.

The genetic disorders that involve single peroxisomal enzymes usually have clinical manifestations that are more restricted and present subsequent to the neonatal period and not infrequently in adolescents or adults. The clinical manifestations may be related to the biochemical defect. For instance, the primary adrenal insufficiency of X-ALD is caused by accumulation of very long chain fatty acids (VLCFA) in the adrenal cortex, and the peripheral neuropathy in Refsum disease is caused by the accumulation of phytanic acid in Schwann cells and myelin.

PBD WITH MILDER OR ATYPICAL PHENOTYPES.

Newborn infants with *Zellweger syndrome* show striking and consistent abnormalities that are easily recognized. Of central diagnostic importance are the typical facial appearance (high forehead, unslanting palpebral fissures, hypoplastic supraorbital ridges, and epicanthal folds; Fig. 75–3), severe weakness and hypotonia, neonatal seizures, and eye abnormalities (cataracts, glaucoma, corneal clouding, Brushfield spots, pigmentary retinopathy, and optic nerve dysplasia). Because of the hypotonia and “mongoloid” appearance, Down syndrome may be suspected. Infants with Zellweger syndrome rarely live more than a few months. More than 90% show postnatal growth failure. Table 75–2 lists the main clinical abnormalities.

Patients with *neonatal ALD* show fewer and occasionally no dysmorphic features. Neonatal seizures occur frequently. Some degree of psychomotor development is present; function remains in the severely or profoundly retarded range, and development may regress after 3–5 yr of age, probably from a progressive leukodystrophy. Several patients are now in a stable, albeit disabled, state in their 3rd or 4th decade. Enlarged liver and impaired liver function, pigmentary degeneration of the retina, and severely impaired hearing are invariably present. Adrenocortical function is usually impaired, but overt Addison disease is rare. Chondrodysplasia punctata and renal cysts are absent.

Patients with *infantile Refsum disease* have survived to the 2nd decade or longer. They are able to walk, although gait may be ataxic and broad based. Cognitive function is in the severely retarded range. All have sensorineural hearing loss and pigmentary degeneration of the retina. They have moderately dysmorphic features that may include epicanthal folds, a flat bridge of the nose, and low-set ears. Early hypotonia and enlarged liver with impaired function are common. Levels of plasma cholesterol and high- and low-density lipoprotein are often moderately reduced. Chondrodysplasia punctata and renal cortical cysts are absent. Postmortem study in infantile Refsum disease reveals micronodular liver cirrhosis and small hypoplastic adrenals. The brain shows no malformations, except for severe hypoplasia of the cerebellar granule layer and ectopic locations of the Purkinje cells in the molecular layer. The mode of inheritance is autosomal recessive.

Some patients with PBD disorders have milder and atypical phenotypes. They may present with peripheral neuropathy or with retinopathy, impaired vision, or cataracts in childhood, adolescence, or adulthood and have been diagnosed to have Charcot-Marie Tooth disease or Usher syndrome. Some patients have survived to the fifth decade.

Rhizomelic Chondrodysplasia Punctata. Rhizomelic chondrodysplasia punctata (RCDP) is characterized by the presence of stippled foci of calcification within the hyaline cartilage and is associated with dwarfing, cataracts (72%), and multiple malformations due to contractures. Vertebral bodies have a coronal cleft filled by cartilage that is a result of an embryonic arrest. Disproportionate short stature affects the proximal parts of the extremities (Fig. 75–4*A*). Radiologic abnormalities consist of shortening of the proximal limb bones, metaphyseal cupping, and disturbed ossification (see Fig. 75–4*B*). Height, weight, and head circumference are less than the 3rd percentile, and these children are severely retarded mentally. Skin changes such as those observed in ichthyosiform erythroderma are present in about 25% of patients.

Isolated Defects of Peroxisomal Fatty Acid Oxidation. The disorders labeled B1 through B3 (see Box 75–1) each involve

Figure 75.2-3 Four patients with Zellweger cerebrohepatorenal syndrome. Note the high forehead, epicanthal folds, and hypoplasia of supraorbital ridges and midface. (Courtesy of Hans Zellweger, MD.)

one of three enzymes involved in peroxisomal fatty acid oxidation. Their clinical manifestations resemble those of the Zellweger syndrome/neonatal ALD/infantile Refsum disease continuum; they can be distinguished from disorders of peroxisome biogenesis by laboratory tests. Defects of bifunctional enzyme are common and are found in approximately 15% of patients with the Zellweger syndrome/neonatal ALD/infantile Refsum disease phenotype. Patients with isolated acyl-coenzyme

Figure 75.2-4 *A*, A newborn infant with RCDP. Note the severe shortening of the proximal limbs, the depressed bridge of the nose, hypertelorism, and widespread scaling skin lesions. *B*, Note the marked shortening of the humerus and epiphyseal stippling at the shoulder and the elbow joints. (Courtesy of John P. Dorst, MD.)

A (CoA) oxidase deficiency have a somewhat milder phenotype that resembles that of neonatal ALD. Only a single patient with peroxisomal thiolase deficiency has been described. This patient had Zellweger syndrome phenotype.

Isolated Defects of Plasmalogen Synthesis. Plasmalogens are lipids in which the first carbon of glycerol is linked to an alcohol rather than a fatty acid. They are synthesized through a complex series of reactions, the first two steps of which are catalyzed by the peroxisomal enzymes dihydroxyacetone phosphate alkyl

transferase and synthase. Deficiency of either of these enzymes (B4 and B5 in Box 75–1) leads to a phenotype that is clinically indistinguishable from the peroxisomal import disorder rhizomelic chondrodysplasia punctata. This latter disorder is caused by a defect in *PEX7*, the receptor for peroxisome targeting sequence 2. It shares the severe deficiency of plasmalogens with disorders B4 and B5, but in addition has defects of phytanic oxidation. The fact that disorders B4 and B5 are associated with the full phenotype of rhizomelic chondrodysplasia punctata suggests that a deficiency of plasmalogens is sufficient to produce it.

Classic Refsum Disease. The defective enzyme (phytanoyl-CoA oxidase) is localized to the peroxisome. The manifestation of classic Refsum disease includes impaired vision from retinitis pigmentosa, ichthyosis, peripheral neuropathy, ataxia, and occasionally cardiac arrhythmias. In contrast to infantile Refsum disease, cognitive function is normal and there are no congenital malformations. Classic Refsum disease often does not manifest until young adulthood, but visual disturbances, such as night blindness, ichthyosis, and peripheral neuropathy may already be present in childhood and adolescence. Early diagnosis is important because institution of a phytanic acid–restricted diet can reverse the peripheral neuropathy and prevent the progression of the visual and central nervous system manifestations.

2-Methylacyl-CoA Racemase Deficiency. This disorder is caused by an enzyme defect that leads to the accumulation of the branched-chain fatty acids (phytanic and pristanic acid) and bile acids. Patients present with adult-type peripheral neuropathy and may also have pigmentary degeneration of the retina.

Laboratory Findings.

Laboratory tests for peroxisomal disorders can be viewed at three levels of complexity.

LEVEL 1: DOES THE PATIENT HAVE A PEROXISOMAL DISORDER?

This can be resolved by noninvasive tests that are generally available (Table 75–3). Measurement of plasma VLCFA is the most commonly used assay. Whereas plasma VLCFA levels are elevated in many patients with peroxisomal disorders, this is not always the case. The most important exception is RCDP, in which VLCFA levels are normal but plasma phytanic acid levels are increased and red blood cell plasmalogen levels are reduced. In some other peroxisomal disorders the biochemical abnormalities are still more restricted. Therefore, a panel of tests is recommended and includes plasma levels of VLCFA and of phytanic, pristanic, and pipecolic acids and levels of plasmalogens in red blood cells. Tandem mass spectrometry techniques also permit convenient quantitation of bile acids in plasma and urine. This panel of tests can be performed on 2-mL samples of venous blood and permits detection of most peroxisomal disorders, and normal results make the presence of a peroxisomal disorder unlikely.

LEVEL 2: WHAT IS THE PRECISE NATURE OF THE PEROXISOMAL DISORDER?

Table 75–3 lists the main biochemical

TABLE 75.2-3 -- Peroxisomal Disorders That Involve Fatty Acid Oxidation: Diagnostic Assays

Disease	Assay		Finding
Zellweger syndrome	Plasma	VLCFA	Increased
Neonatal adrenoleukodystrophy		Phytanic acid	Age-dependent increase
Infantile Refsum disease		Pristanic acid	Age-dependent increase
		Pipecolic acid	Increased
		Bile acid	Increased, abnormal pattern
	RBCs, Fibroblasts	Plasmalogen levels	Variably decreased
		VLCFA levels	Increased
		VLCFA oxidation	Decreased
		Plasmalogen synthesis	Decreased
		Phytanic, pristanic oxidation	Decreased
		Catalase localization	Cytosolic
		Immunocytochemistry	Peroxisomes absent
		Complementation	See Table 75–1
		DNA	See Table 75–1
Rhizomelic chondrodysplasia punctata	Plasma	Phytanic acid	Increased
		VLCFA	Normal
	RBCs	Plasmalogen levels	Decreased
	Fibroblasts	Plasmalogen synthesis	Decreased
		Phytanic acid oxidation	Decreased
		DNA	*PEX7* defect

X-linked ALD hemizygote	Plasma	VLCFA	Increased
	Fibroblasts	VLCFA levels	Increased
		VLCFA oxidation	Decreased
		ALDP immunoreactivity	Absent 70%
		DNA	*ABCD1* mutation
X-linked ALD heterozygote	Plasma	VLCFA	Variable increase in 85%
	Fibroblasts	VLCFA levels	Variable increase in 90%
		ALDP immunoreactivity	Variable decrease
		DNA	*ABCD1* mutation
Bifunctional enzyme defect	Plasma	VLCFA	Increased
		Phytanic acid	Increased
		Pristanic acid	Increased
		Bile acids	Increased, abnormal pattern
	Fibroblasts	VLCFA levels	Increased
		Pristanic acid oxidation	Decreased
		Catalase localization	Peroxisomal
		Enzyme	D-bifunctional protein deficiency
Acyl-CoA oxidase deficiency	Plasma	VLCFA	Increased
	Fibroblasts	VLCFA levels	Increased
		VLCFA oxidation	Decreased
		Enzyme	Acyl-CoA oxidase defect
2-Methyl acyl-CoA racemase deficiency	Plasma	Pristanic acid	Increased
		Bile acids	Increased, abnormal pattern
	Fibroblasts	Pristanic acid oxidation	Decreased
		Enzyme	2-Methyl acyl CoA oxidase defect
Classic Refsum disease	Plasma	Phytanic acid	Increased
		Pristanic acid	Decreased
	Fibroblasts	Enzyme	Phytanoyl-CoA deficiency

VLCFA = very long chain fatty acids; ALD = adrenoleukodystrophy.

abnormalities in the various peroxisomal disorders. When combined with the clinical presentation the just mentioned panel of tests is often sufficient to identify the precise nature of the defect. Elevated plasma VLCFA levels permit the precise diagnosis of X-ALD in male patients. Marked reduction of erythrocyte plasmalogen levels combined with elevated plasma phytanic acid permits precise diagnosis in a patient with the clinical features of RCDP. Classic Refsum disease can be diagnosed by demonstration of increased plasma phytanic acid combined with normal or reduced levels of pristanic acid levels.

Precise identification of some peroxisomal disorders may require more extensive studies in cultured skin fibroblasts. This may be required for the differentiation of PBD from defects in bifunctional enzyme. In PBD patients peroxisomes are absent and catalase is in the soluble fraction, whereas in bifunctional enzyme defect, peroxisomes are present and catalase is in the particulate fraction. Fibroblast studies are required to identify the nature of the molecular defect in PBD. Whether such specialized studies are clinically warranted depends on individual circumstances. Precise definition of the defect in a proband may improve the precision of prenatal diagnosis in at-risk pregnancies, and it is required for carrier detection. It is also of value in

setting prognosis. For example, precise characterization is of prognostic value in patients with *PEX1* defects. This defect is present in about 60% of PBD patients, and about half of the *PEX1* defects have the G843D allele, which is associated with a significantly milder phenotype than is found in other mutations.

LEVEL 3: WHAT IS THE MOLECULAR DEFECT?

Table 75–1 shows that the molecular defects in most of the PBD have been defined. Definition of the molecular defect in a proband would speed prenatal diagnosis and is required for carrier detection. Even though mutation analysis of PBD is technically feasible it is not available on a service basis but may become so in the future.

Diagnosis.

There are several noninvasive laboratory tests that permit precise and early diagnosis of peroxisomal disorders (see Table 75–3). The challenge in PBD is to differentiate them from the large variety of other conditions that can cause hypotonia, seizures, failure to thrive, or dysmorphic features. Experienced clinicians can readily recognize classic Zellweger syndrome by its clinical manifestations. PBD patients often do not show the full clinical spectrum of disease and may be identifiable only by

laboratory assays. Clinical features that may serve as indications for these diagnostic assays include severe psychomotor retardation; weakness and hypotonia; dysmorphic features; neonatal seizures; retinopathy, glaucoma, or cataracts; hearing deficits; enlarged liver and impaired liver function; and chondrodysplasia punctata. The presence of one or more of these abnormalities increases the likelihood of this diagnosis. Atypical milder forms presenting as peripheral neuropathy have also been described.

Some patients with the isolated defects of peroxisomal fatty acid oxidation (group B) resemble those with group A disorders and can be detected by the demonstration of abnormally high levels of VLCFA.

Patients with RCDP must be distinguished from patients with other causes of chondrodysplasia punctata. In addition to warfarin embryopathy and Zellweger syndrome, these disorders include the milder autosomal dominant form of chondrodysplasia punctata *(Conradi-Hunermann syndrome)*, which is characterized by longer survival, absence of severe limb shortening, and usually intact intellect; an X-linked dominant form; and an X-linked recessive form associated with a deletion of the terminal portion of the short arm of the X chromosome. RCDP is suspected clinically because of the shortness of limbs, psychomotor retardation, and ichthyosis. The most decisive laboratory test is the demonstration of abnormally low plasmalogen levels in red blood cells and an impaired capacity to synthesize plasmalogens in cultured skin fibroblasts. These biochemical defects are not present in other types of chondrodysplasia punctata. Chondrodysplasia punctata may also be associated with a defect of 3ß-hydroxysteroid-$?^{8}$,$?^{7}$ -isomerase, an enzyme involved in biosynthesis of cholesterol.

Complications.

Patients with Zellweger cerebrohepatorenal syndrome have multiple disabilities involving muscle tone, swallowing, cardiac abnormalities, liver disease, and seizures. These conditions are treated symptomatically, but the prognosis is poor, and most patients succumb during the first few months of life. Patients with rhizomelic chondrodysplasia punctata may develop quadriparesis owing to compression at the base of the brain.

Prevention.

See Chapters 72 and 73 .

Treatment.

The most effective therapy is the dietary treatment of classic Refsum disease with a phytanic acid-restricted diet.

For patients with the somewhat milder variants of the peroxisome import disorders, considerable success has been achieved with multidisciplinary early intervention, including physical and occupational therapy, hearing aids, alternative communication, nutrition, and support for the parents. Although most patients continue to function in the profoundly or severely retarded range, some make significant gains in self-help skills, and several are in stable condition in their teens or even early 20s.

Studies to mitigate some of the secondary biochemical abnormalities include the oral administration of docosahexaenoic acid in a dosage of 50–100?mg/24?hr either as the ethyl ester or in the form of a triglyceride in which one of the fatty acids has been replaced by docosahexaenoic acid. This therapy normalizes the plasma and erythrocyte levels of this substance, which has important physiologic functions in retina and brain, but the levels of which are reduced greatly in patients with disorders of peroxisome biogenesis because the last step of its synthesis takes place in the peroxisome. There are anecdotal reports of clinical improvement. The oral administration of cholic acid and chenodeoxycholic acid in a dosage of 100–250?mg/24?hr, with the aim of reducing the levels of presumably toxic bile acid intermediates, may be effective.

Genetic Counseling.

All the peroxisomal disorders can be diagnosed prenatally in the 1st or 2nd trimester, except for hyperoxaluria type 1. The tests are similar to those described for postnatal diagnosis (see Table 75–3) and use chorionic villus sampling or amniocytes. More than 300 pregnancies have been monitored, and more than 60 affected fetuses have been identified without diagnostic error. Because of the 25% recurrence risk, couples, with an affected child, must be advised about the availability of prenatal diagnosis. Heterozygotes can be identified in X-linked adrenoleukodystrophy and in those disorders in which the molecular defect has been identified (see Table 75–1).

75.3 ADRENOLEUKODYSTROPHY (X-LINKED)

X-linked ALD is a genetically determined disorder associated with the accumulation of saturated VLCFA and a progressive dysfunction of the adrenal cortex and nervous system white matter.

Etiology.

The key biochemical abnormality is the tissue accumulation of unbranched saturated VLCFA, with a carbon chain length of 24 or more. Excess hexacosanoic acid (C26:0) is the most striking and characteristic feature. This accumulation of fatty acids is caused by genetically deficient peroxisomal degradation of fatty acid. The key biochemical defect involves the impaired function of peroxisomal lignoceroyl-CoA ligase, the enzyme that catalyzes the formation of the CoA derivative of VLCFA. The gene that is defective *(ABCD1)* codes for a peroxisomal membrane (ALDP). More than 400 distinct mutations have been identified, and most families have a mutation that is “private” (unique to that kindred). The gene has been mapped to chromosome Xq28. The mechanism by which the ALDP defect leads to VLCFA accumulation and the pathology of X-ALD is unknown.

Epidemiology.

The minimum incidence of X-ALD in males is 1:21,000, and the combined incidence of X-ALD males and heterozygous females in the general population is estimated to be 1:17,000. All races are affected. The various phenotypes often occur in members of the same kindred.

Pathology.

Characteristic lamellar cytoplasmic inclusions can be demonstrated with the electron microscope in adrenocortical cells, testicular Leydig cells, and nervous system macrophages. These inclusions probably consist of cholesterol esterified with VLCFA. They are most prominent in cells of the zona fasciculata of the adrenal cortex, which at first are distended with lipid and later atrophy.

The nervous system can display two types of lesions. In the severe childhood cerebral form and in the rapidly progressive adult forms, demyelination is associated with an inflammatory response manifested by the accumulation of perivascular

lymphocytes that is most intense in the parieto-occipital region. In the slowly progressive adult form, adrenomyeloneuropathy (AMN), the main finding is a distal axonopathy that affects the long tracts in the spinal cord. The inflammatory response is mild or absent.

Pathogenesis.

The adrenal dysfunction is probably a direct consequence of the accumulation of VLCFA. The cells in the zona fasciculata are distended with abnormal lipids. Cholesterol esterified with VLCFA is relatively resistant to adrenocorticotropic hormone (ACTH)-stimulated cholesterol ester hydrolases, and this limits the capacity to convert cholesterol to active steroids. In addition, C26:0 excess increases the viscosity of the plasma membrane and this may interfere with receptor and other cellular functions.

There is no correlation between the neurologic phenotype and the nature of the mutation or the severity of the biochemical defect as assessed by plasma levels of VLCFA or between the degree of adrenal and nervous system involvement. The severity of the illness and rate of progression correlate with the intensity of the inflammatory response. The inflammatory response may be cytokine mediated and may involve an autoimmune response triggered in an unknown way by the excess of VLCFA. A CD1 lipid antigen has been implicated. Approximately half of the patients do not experience the inflammatory response. A modifier gene that sets the “thermostat” for the inflammatory response is postulated.

Clinical Manifestations.

There are five relatively distinct phenotypes, three of which present in childhood with symptoms and signs. In all the phenotypes, development is usually normal during the first 3–4 yr.

In the *childhood cerebral* form of ALD, symptoms are first noted most commonly between the ages of 4 and 8 yr (3 yr at the earliest). The most common initial manifestations are hyperactivity, which is often mistaken for an attention deficit disorder, and worsening school performance in a child who had previously been a good student. Auditory discrimination is often impaired, although tone perception is preserved. This may be evidenced by difficulty in using the telephone and greatly impaired performance on intelligence tests in items that are presented verbally. Spatial orientation is often impaired. Other initial symptoms are disturbances of vision, ataxia, poor handwriting, seizures, and strabismus. Visual disturbances often are due to involvement of the cerebral cortex, which leads to variable and seemingly inconsistent visual capacity. Seizures occur in nearly all patients and may represent the first manifestation of the disease. Some patients present with increased intracranial pressure or with unilateral mass lesions. Impaired cortisol response to ACTH stimulation is present in 85% of patients, and mild hyperpigmentation is noted. However, in most patients with this phenotype, adrenal dysfunction is recognized only after the condition is diagnosed because of the cerebral symptoms. Cerebral childhood ALD tends to progress rapidly with increasing spasticity and paralysis, visual and hearing loss, and loss of ability to speak or swallow. The mean interval between the first neurologic symptom and an apparently vegetative state is 1.9 yr. Patients may continue in this apparently vegetative state for 10 yr or more.

Adolescent ALD designates patients who experience neurologic symptoms between the ages of 10 and 21 yr. The manifestations resemble those of childhood cerebral ALD except that progression is slower.

About 10% of patients present acutely with status epilepticus, adrenal crisis, acute encephalopathy, or coma.

Adrenomyeloneuropathy first manifests in late adolescence or adulthood as a progressive paraparesis caused by long tract degeneration in the spinal cord. Approximately one half of the patients also have involvement of the cerebral white matter.

The “Addison only” phenotype is an important and underdiagnosed condition. Of male patients with Addison disease, 25% may have the biochemical defect of ALD. Many of these patients have intact neurologic systems, whereas others have subtle neurologic signs. Many acquire adrenomyeloneuropathy in adulthood.

The term *asymptomatic ALD* is applied to persons who have the biochemical defect of ALD but are free of neurologic or endocrine disturbances. Nearly all persons with the gene defect eventually become symptomatic. A few have remained asymptomatic even in the 6th or 7th decade.

Approximately 50% of female heterozygotes acquire a syndrome that resembles adrenomyeloneuropathy but is milder and of later onset. Adrenal insufficiency is rare.

Laboratory and Radiographic Findings.

The most specific and important laboratory finding is the demonstration of abnormally high levels of VLCFA in plasma, red blood cells, or cultured skin fibroblasts. The test should be performed in a laboratory that has experience with this specialized procedure. Positive results are obtained in all male patients with X-linked ALD and in approximately 85% of female carriers of X-linked ALD. Mutation analysis is the most reliable method for the identification of carriers.

CT AND MRI.

Patients with childhood cerebral or adolescent ALD show cerebral white matter lesions that are characteristic with respect to location and attenuation patterns on MRI. In 80% of patients, the lesions are symmetric and involve the periventricular white matter in the posterior parietal and occipital lobes. About 50% show location of a garland of accumulated contrast material adjacent and anterior to the posterior hypodense lesions (Fig. 75–5*A*). This zone corresponds to the zones of intense perivascular lymphocytic infiltration where the blood-brain barrier breaks down. In 12% of patients, the initial lesions are frontal. Unilateral lesions that produce a mass effect suggestive of a brain tumor may occur. MRI provides a clearer delineation of normal and abnormal white matter than does CT and may demonstrate abnormalities missed by CT (see Fig. 75–5*B*).

IMPAIRED ADRENAL FUNCTION.

More than 85% of patients with the childhood form of ALD have elevated levels of ACTH in plasma and a subnormal rise of cortisol levels in plasma following intravenous injection of 250?µg of $ACTH_{1B}{}^{z}$ 4 (Cortrosyn).

Diagnosis and Differential Diagnosis.

The earliest manifestations of childhood cerebral ALD are difficult to distinguish from the more common attention deficit disorders or learning disabilities. Rapid progression, signs of dementia, or difficulty in auditory discrimination suggest ALD. Even in early stages, CT or MRI may show strikingly abnormal changes. Other leukodystrophies (see Chapters 592.5 and 604.10) or multiple sclerosis (see Chapter 592.5) may mimic these radiographic findings.

Figure 75.3-5 *A*, Contrast-enhanced CT abnormalities in ALD with typical parieto-occipital location, showing symmetric bilateral hypodense inactive zones (Ho). The enhancing active periphery zone of hypodensity is demarcated by *arrows*. Compare the anterior zone of hypodensity *(arrowheads)* with that on the MRI in *B*. CC = corpus callosum. *B*, MRI of the same patient and area shown by CT. MRI T2-weighted image shows a high-intensity signal of the abnormally bright parieto-occipital white matter. Subcortical involvement is better identified on MRI. Separation of active zones may be better appreciated by CT, because both inactive and active zones are seen at high-signal areas on MRI. However, it is assumed that such major distinctions afforded by CT will also be demonstrable when IV enhancement (paramagnetic enhancement) becomes readily available. Note the hypodense involvement of CT (*arrowheads* and *arrows* in *A*) compared with the well-resolved lesions on MRI in *B*. (From Kumar AJ, Rosenbaum WE, Naidu S, et al: Adrenoleukodystrophy: Correlating MR imaging with CT. *Radiology* 1987;165:697.)

Definitive diagnosis depends on demonstration of VLCFA excess, which occurs only in X-linked ALD and the other peroxisomal disorders. The latter may be distinguished from X-linked ALD by their clinical presentation during the neonatal period.

Cerebral forms of ALD may present as increased intracranial pressure and unilateral mass lesions. These have been misdiagnosed as gliomas, even after brain biopsy, and several patients have received radiotherapy before the correct diagnosis was made. Measurement of VLCFA in plasma or brain biopsy specimens is the most reliable differentiating test.

Adolescent or adult cerebral ALD can be confused with psychiatric disorders, dementing disorders, or epilepsy. The first clue to the diagnosis of ALD may be the demonstration of white matter lesions by CT or MRI; assays of VLCFA are confirmatory.

ALD cannot be distinguished clinically from other forms of Addison disease; it is recommended that assays of VLCFA levels be performed in all male patients with Addison disease. ALD patients usually never have antibodies to adrenal tissue in their plasma.

Complications.

An avoidable complication is the occurrence of adrenal insufficiency. The most difficult neurologic problems are those related to bed rest, contracture, coma, and swallowing disturbances. Other complications involve behavioral disturbances and injuries associated with defects of spatial orientation, impaired vision and hearing, and seizures.

Treatment.

Corticosteroid replacement for adrenal insufficiency or adrenocortical hypofunction is effective (see Chapter 569). It may be lifesaving and increase general strength and well being, but it does not alter the course of the neurologic disability.

BONE MARROW TRANSPLANTATION.

Bone marrow transplantation (BMT) benefits patients who show early evidence of the inflammatory demyelination that is characteristic of the rapidly progressive neurologic disability in boys and adolescents with the cerebral X-ALD phenotype. BMT is a high-risk procedure, and patients must be selected with great care. The mechanism of the beneficial effect is incompletely understood. Bone marrow–derived cells do express ALDP, the protein that is deficient in X-ALD, and approximately 50% of brain microglial cells are bone marrow derived. It is possible that replacement of these cells by cells that contain the normal gene changes the brain milieu sufficiently to correct the brain metabolic disturbance. The favorable effect may also be caused by modification of the brain inflammatory response. Five to 10 yr follow-up of boys and adolescents who had early cerebral involvement has shown stabilization and, in some instances, improvement. On the other hand BMT has not shown favorable effects in patients who had already severe brain involvement and may accelerate disease progression under these circumstances. The nonverbal IQ has been found to be of predictive value, and transplant is not recommended in patients with nonverbal IQ significantly below 80. Unfortunately, in more than half the patients who are diagnosed because of neurologic symptoms, the illness is so advanced that they are not candidates for transplant.

Consideration of BMT is most relevant in neurologically asymptomatic or mildly involved patients. Screening at-risk relatives of symptomatic patients identifies these patients most frequently, and less frequently by measurement of plasma VLCFA levels in patients with Addison disease. Because of its risk (10–20% mortality), and the fact that up to 50% of untreated patients with X-ALD do not develop inflammatory brain demyelination, transplant is not recommended in patients who are free of demonstrable brain involvement. The MRI is also of key importance for the crucial decision of whether transplant should be performed. MRI abnormalities precede clinically evident neurologic or neuropsychologic abnormalities. The brain MRI should be monitored at 6-mo to 1-yr intervals in neurologically asymptomatic boys and adolescents between the ages of

---

3–15 yr. If the MRI is normal, BMT is not indicated. If brain MRI abnormalities develop, the patient should be evaluated at 3-mo intervals to determine if the abnormality is progressive, in combination with careful neurologic and neuropsychologic evaluation; and if early progressive involvement is confirmed, transplant should be considered. Magnetic resonance spectroscopy improves the capacity to determine whether the brain involvement is progressive. It is not known whether BMT has a favorable effect on the noninflammatory spinal cord involvement in adults with the adrenomyeloneuropathy phenotype.

OTHER THERAPIES.

Oral administration of a 4:1 mixture of glyceryl trioleate and glyceryl trierucate (Lorenzo's oil) when combined with a reduced fat intake, normalizes the levels of VLCFA within 4 wk. It has not been found to be effective in patients who are already symptomatic, but it has some preventive effect in asymptomatic boys who are less than 6 yr old. Interferon-ß and immunosuppressive therapies have not been found to be effective. Therapies with lovastatin and with 4-phenylbutyrate have been proposed and are being tested in clinical trials. Gene therapy has shown promise in cultured cells and the mouse model of X-ALD but is not yet available for human trial.

SUPPORTIVE THERAPY.

The progressive behavioral and neurologic disturbances associated with the childhood form of ALD are extremely difficult for the family. ALD patients require the establishment of a comprehensive management program and partnership among the family, physician, visiting nursing staff, school authorities, and counselors. In addition, parent support groups are often helpful (United Leukodystrophy Foundation, 2304 Highland Drive, Sycamore, IL 60178). Communication with school authorities is important because under the provisions of Public Law 94–142, children with ALD qualify for special services as “other health impaired” or “multihandicapped.” Depending on the rate of progression of the disease, special needs might range from relatively low-level resource services within a regular school program to home and hospital-based teaching programs for children who are not mobile.

Management challenges vary with the stage of the illness. The early stages are characterized by subtle changes in affect, behavior, and attention span. Counseling and communication with school authorities are of prime importance. Changes in the sleep-wake cycle can be benefited by the judicious use at night of sedatives such as chloral hydrate (10–50?mg/kg), pentobarbital (5?mg/kg), or diphenhydramine (2–3?mg/kg).

As the leukodystrophy progresses, the modulation of muscle tone and support of bulbar muscular function are major concerns. Baclofen in gradually increasing doses (5?mg bid to 25?mg qid) is the most effective pharmacologic agent for the treatment of acute episodic painful muscle spasms. Other agents may also be used, with care being taken to monitor the occurrence of side effects and drug interactions. As the leukodystrophy progresses, bulbar muscular control is lost. Although initially this can be managed by changing the diet to soft and pureed foods, most patients eventually require a nasogastric tube or a gastrostomy. At least one third of patients have focal or generalized seizures that usually readily respond to standard anticonvulsant medications.

Genetic Counseling and Prevention.

Genetic counseling and primary and secondary prevention of X-ALD are of crucial importance. Extended family screening should be offered to all at-risk relatives of symptomatic patients; one program led to the identification of more than 250 asymptomatic affected males and 1,200 women heterozygous for X-ALD. The plasma assay permits reliable identification of affected males in whom plasma VLCFA levels are increased already on the day of birth. Identification of asymptomatic males permits institution of steroid replacement therapy when appropriate and prevents the occurrence of adrenal crisis, which may be fatal. Monitoring of brain MRI also permits identification of patients who are candidates for bone marrow transplant at a stage when this procedure has the greatest chance of success. Plasma VLCFA assay is recommended in all male patients with Addison disease. X-ALD has been shown to be the cause of adrenal insufficiency in over 25% of boys with Addison disease of unknown cause. Identification of women heterozygous for X-ALD is more difficult than that of affected males. Plasma VLCFA levels are normal in 15–20% of heterozygous women, and failure to note this has led to serious errors in genetic counseling. If VLCFA levels are normal both in plasma and cultured skin fibroblasts, the risk of false-negative results is reduced but not eliminated. DNA analysis permits accurate identification of carriers provided that the mutation has been defined in a family member. Mutation analysis is available on a service basis.

Prenatal diagnosis of affected male fetuses can be achieved by measurement of VLCFA levels in cultured amniocytes or chorionic villus cells and by mutation analysis. Whenever a new patient with X-linked ALD is identified, a detailed pedigree should be constructed, and efforts should be made to identify all at-risk female carriers and affected males. These investigations should be accompanied by careful and sympathetic attention to social, emotional, and ethical issues during counseling.

75.4 Disorders of Lipoprotein Metabolism and Transport

Andrew M. Tershakovec
Daniel J. Rader

EPIDEMIOLOGY OF BLOOD LIPIDS AND CARDIOVASCULAR DISEASE

There is an association between fat intake and cholesterol levels and adult coronary heart disease (CHD) mortality. Adult cardiovascular disease has its roots in childhood; for example, young American casualties in the Korean and Vietnam wars were found to have a significant prevalence of atherosclerosis. In the Johns Hopkins Precursors Study, cholesterol levels measured in young men in their early 20s were predictive of the risk of CHD developing 3 to 4 decades later. The strongest data linking factors in childhood with adult CHD come from the Bogalusa Heart Study and the Pathobiological Determinants of Atherosclerosis in Youth Research Group. These surveys have found significant correlations between early atherosclerotic changes, identified at autopsy of children and young adults, and both total and low-density lipoprotein (LDL) cholesterol levels.

Although there are no data directly linking cholesterol levels in children with adult heart disease, most of the evidence suggests that such an association exists. Children at risk for the development of premature atherosclerosis in adulthood (those with elevated cholesterol levels) should be identified early in life to try to reduce the associated risk of heart disease. Children, with cholesterol levels greater than the 75th percentile, should be considered hypercholesterolemic and potentially at risk for adult heart disease. Although many experts agree that hypertriglyceridemia is also a risk factor for premature CHD, the risk is less well defined than the risk associated with hypercholesterolemia.

Clinical Trials of Cholesterol Reduction.

Multiple trials in adults assessed the impact of cholesterol reduction on a quantitative measure of atherosclerotic disease or on clinical cardiovascular events. A number of trials tested whether treatment to lower cholesterol would influence the course of angiographic coronary disease. These trials have demonstrated that cholesterol reduction resulted in reduced angiographic progression of coronary disease and even modest regression in some cases. The angiographic differences between treated and control groups has generally been small and by themselves of uncertain clinical significance. However, the reductions in clinical cardiovascular events in the

treated groups in many of these studies were surprising and disproportionate to the modest differences in measurable atherosclerosis.

Several secondary prevention trials in adults with clinical end points have confirmed that cholesterol reduction in the setting of established coronary disease is highly effective in reducing cardiovascular events and total mortality. These trials have used a wide variety of interventions, including diet, niacin, bile acid sequestrants, partial ileal bypass surgery, and, most effectively, the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins). Trials with statins that enrolled coronary artery disease patients with average cholesterol levels also demonstrated significant benefit.

Primary prevention of CHD is important, as approximately one fourth to one third of first myocardial infarctions result in death. The Oslo study, which focused on diet intervention and smoking cessation, demonstrated a 47% decrease in fatal and nonfatal myocardial infarction. Three primary prevention trials using different lipid-lowering drugs (clofibrate, cholestyramine, and gemfibrozil) produced mixed results, generally lowering CHD mortality but not overall mortality. The West of Scotland Coronary Prevention Trial demonstrated that treatment with pravastatin resulted in reduced nonfatal myocardial infarctions and CHD mortality, as well as in total mortality, in relatively high-risk men with hypercholesterolemia but no prior history of coronary artery disease. The Air Force/Texas Coronary Artery Prevention Study demonstrated that treatment with lovastatin reduced major coronary events in relatively average-risk men and women with only moderately elevated cholesterol levels, relatively low high-density lipoprotein (HDL) cholesterol levels, and no evidence of baseline vascular disease. These trials have clearly established that drug therapy for hypercholesterolemia is safe and effective in reducing coronary events in adults without prior evidence of CHD.

PLASMA LIPOPROTEIN METABOLISM AND TRANSPORT

Cholesterol and triglycerides are transported in the circulation in macromolecular complexes termed *lipoproteins*; the protein components of the complexes are called *apolipoproteins*. Dietary lipoproteins (chylomicrons) are formed in and secreted by the small intestine; other lipoproteins (very low density lipoproteins, VLDL) are synthesized in the liver; still others (HDL) are secreted as nascent particles by the liver and small intestine and reach their mature form in the circulation only after exchange of components with other circulating lipoproteins or with tissues.

Transport of Exogenous (Dietary) Lipids.

After ingestion of a fat-containing meal and hydrolysis of esterified lipids by intestinal and pancreatic lipases, free fatty acids and cholesterol are re-esterified in the intestinal epithelium to form triglycerides and cholesteryl esters, respectively. These lipids are then packaged together with phospholipids, free cholesterol, and the apolipoproteins apoA-I, apo A-IV, and apoB-48 to form chylomicrons (Fig. 75–6). The chylomicrons are then secreted into the intestinal lymph and pass through the thoracic duct into the peripheral circulation. In the circulation, chylomicrons acquire additional apolipoproteins, mainly apoE and several forms of apoC. Triglycerides, which constitute most of the chylomicron mass, are hydrolyzed by lipoprotein lipase at the capillary endothelium; apoC-II is a required cofactor for lipoprotein lipase. The free fatty acid products of this hydrolysis are transferred primarily to adipose tissue for storage as triglycerides or to muscle tissue for ß-oxidation. The lipoprotein particles, now smaller and denser because they have lost much of their triglyceride content, are called *chylomicron remnants*. They have retained most of their cholesteryl ester content, have transferred some of their apolipoproteins (apoCs and apoA-I) to HDL, and have become enriched with respect to their apoE content. These remnants are bound and internalized in part via hepatic membrane receptors specific for apoE on the particles. By this mechanism, dietary

Figure 75.4-6 Pathway of chylomicron metabolism in human plasma. Fatty acids (FA) and cholesterol (C) are esterified in the intestinal mucosa to form triglycerides (TG) and cholesteryl esters (CE), respectively. They combine with apoA and apoB-48 to form chylomicrons, which are secreted into the circulation: TG *(shaded area)* and CE *(black area)*. Chylomicrons undergo lipolysis in the capillary endothelium near adipose tissue and muscle tissue, losing TG via lipoprotein lipase (LPL), gaining apoE from HDL, and losing apoA and apoC to HDL. The resultant chylomicron remnants are taken up by hepatic apoE receptors for degradation by lysosomes. (Adapted from Havel RJ: Approach to the patient with hyperlipidemia. *Med Clin North Am* 1982;66:319.)

cholesterol is delivered to the liver, where it plays a role in the regulation of hepatic cholesterol metabolism. Under normal circumstances, chylomicrons and their remnants are very short-lived in the circulation; following a 12-hr fast, there are no chylomicrons or chylomicron remnants remaining in the plasma.

Transport of Endogenous Lipids from the Liver.

The liver secretes a class of lipoproteins called very low density lipoproteins, which contain free and esterified cholesterol, triglycerides, phospholipids, and several apolipoproteins, notably apoB-100, apoCs, and apoE. Like chylomicrons, VLDL exchange apolipoproteins with other circulating particles and deliver free fatty acids to adipose tissue and muscle after hydrolysis of triglycerides by lipoprotein lipase (Fig. 75–7). In the process, they become smaller and denser and are termed *VLDL remnants* or *intermediate-density lipoproteins* (IDL). Some of these remnant particles are taken up via hepatic receptors specific for apoE, whereas some undergo conversion to LDL. Conversion of LDL particles

Figure 75.4-7 Pathways of VLDL and LDL metabolism in human plasma. Triglycerides (TG) and cholesteryl esters (CE) are combined with apoB-100, apoC, and apoE in the liver and then secreted as VLDL, TG *(shaded area)*, and CE *(black area)*. VLDL undergo lipolysis in the capillary endothelium near adipose tissue and muscle tissue, losing TG via lipoprotein lipase (LPL). The resulting VLDL remnants are either converted to low-density lipoproteins (LDL) for transport to peripheral cells via LDL receptor-mediated uptake or are taken up by hepatic receptors. FFA = free fatty acids. (Adapted from Havel RJ: Approach to the patient with hyperlipidemia. *Med Clin North Am* 1982;66:319.)

requires participation of hepatic lipase, which hydrolyzes the remaining triglycerides, as well as some phospholipids. LDL are almost entirely made up of cholesteryl esters and apoB-100. A specific LDL receptor is present on most cell membranes and recognizes, binds, and internalizes LDL. By this mechanism, LDL particles can deliver cholesterol to extrahepatic tissues for use in membrane or steroid hormone synthesis. LDL receptor expression by the liver is a major regulator of plasma LDL

cholesterol levels. LDL particles have a half-life of 3–4 days.

High-Density Lipoprotein and Reverse Cholesterol Transport.

In contrast to chylomicrons and VLDL, which are secreted into the circulation as mature particles, the liver and small intestine secrete HDL as nascent discoidal particles composed primarily of phospholipids and apolipoproteins. Nascent HDL secreted by the small intestine are rich in apoA-I and apoA-IV, whereas those derived from the liver contain predominantly apoA-I, and apoA-II. Nascent lipid-poor apoA-I accepts unesterified cholesterol from tissues via a process that requires the ATP-binding cassette protein A1 (ABCA1), a cellular protein that facilitates the efflux of unesterified cholesterol and phospholipids from cells to apoA-1. Unesterified cholesterol in nascent HDL is esterified by the enzyme lecithin:cholesterol acyltransferase (LCAT), which is present on HDL, forming cholesteryl esters. HDL cholesteryl esters may be selectively taken up by the liver via a hepatic HDL receptor called scavenger receptor class BI (SR-BI). Alternatively, HDL cholesteryl ester may transfer from HDL to VLDL and LDL by the cholesteryl ester transfer protein (CETP), after which it may be taken up by the liver or redistributed to peripheral tissues. Thus, HDL have two pathways by which they return tissue-derived cholesterol to the liver in a process that has been termed *reverse cholesterol transport*. HDL-derived cholesterol is either converted by the liver to bile acids or directly excreted into the bile.

PLASMA LIPID AND LIPOPROTEIN LEVELS

Table 75–4 presents normal plasma cholesterol and triglyceride levels from birth through the first 2 decades of life. During the first few months of life, cholesterol levels increase largely because of changes in LDL. Over the next 15–20 yr, in both males and females, there is little change in the total cholesterol level; the mean value fluctuates around 150–165?mg/dL. Mean LDL cholesterol levels remain slightly less than 100?mg/dL in both males and females during this period. HDL cholesterol levels are comparable in males and females early in life; they remain essentially constant in females but decline markedly in males during the 2nd decade to a level that is maintained through adulthood. Plasma triglyceride levels, in contrast, rise transiently in both males and females in the 1st year, fall to a mean of 50–60?mg/dL in the ensuing few years, and then rise to a mean of approximately 75?mg/dL by age 20 yr. In early adulthood, there is a rise in plasma cholesterol that is almost exclusively caused by an increase in LDL cholesterol. The rate of increase over the next 30 yr is greater in males than in females. When coupled with their lower HDL cholesterol levels, this puts men at much greater risk than women for atherosclerotic heart disease, at least until women reach the age of menopause. Because of the changes in lipid levels with age, it is more appropriate to use age- and gender-specific percentile figures when comparing levels between individuals and over long periods rather than consider absolute cholesterol levels.

Cholesterol levels track over time. Thus, children with high cholesterol levels tend to have higher levels as young adults, whereas those with low levels as children tend to have lower levels as adults. However, this is not always the case. A significant degree of biologic and laboratory variation in cholesterol measurements contributes to this. Lifestyle changes of participants (weight loss, changes in diet) in longitudinal surveys of cholesterol levels in children and young adults may also have

contributed to the lower observed degree of tracking. Surveys in adults have described a decline in the prevalence of hypercholesterolemia, presumably related to a decreasing intake of fat in the diet; however, a disturbing increase in the prevalence of obesity is also occurring. This may balance or overwhelm the positive public health effects of lower cholesterol levels.

Children may have moderately raised cholesterol levels for a variety of reasons. Some primary genetic defects may be associated with only mild alterations in blood lipid levels. Furthermore, there are secondary causes of hyperlipoproteinemia (HLP) (other disease states) that need to be considered. Finally, inappropriate dietary habits, by themselves or by interacting with any of the preceding factors, can contribute to moderately raised cholesterol levels. Although some children suffer from well-defined familial hyperlipidemia, the majority of individuals with hyperlipidemia do not have such specific syndromes. In addition, although those with hyperlipidemia are at increased risk for heart disease, not all hyperlipidemic individuals acquire clinical heart disease.

SCREENING FOR HYPERCHOLESTEROLEMIA

The Expert Panel on Blood Cholesterol Levels in Children and Adolescents of the National Cholesterol Education Program and the American Academy of Pediatrics Committee on Nutrition have recommended that children with a parental history of elevated total cholesterol levels (>240?mg/dL) have their total cholesterol level measured. Children with incomplete or unavailable family histories, or those with other risk factors for CHD (obesity, cigarette smoking, hypertension, diabetes, inactivity, low HDL cholesterol), should be screened at the discretion of the pediatric care provider. Cholesterol measurements have been shown to be relatively unreliable when undertaken in settings without adequate quality assurance. To avoid inaccurately labeling children as hypercholesterolemic, screening should be completed using only reliable laboratories and methods.

Children with total cholesterol levels less than 170?mg/dL require no intervention other than that recommended for the general population and should be re-evaluated in 5 yr. Children whose total cholesterol level is greater than 200?mg/dL should have a fasting lipid profile performed. Those with borderline levels (170–199?mg/dL) should have another total cholesterol measurement, and the two values should be averaged; if the average total cholesterol level in these two determinations is greater than 170?mg/dL, a lipid profile is recommended. The expert panel has likewise recommended that children with a family history of premature coronary heart disease (before the age of 55 yr in a parent or grandparent) should have a lipid profile completed. Lipid profiles of parents and other 1st-degree relatives are necessary to establish whether there is a dominantly inherited defect responsible for the hypercholesterolemia.

A lipid profile (total and HDL cholesterol, triglycerides, calculated LDL cholesterol) is obtained after a 12-hr fast. VLDL cholesterol can be estimated by dividing the triglycerides by 5 (in fasting plasma, most triglycerides are in VLDL and the ratio of triglycerides to cholesterol in VLDL is approximately 5:1). LDL cholesterol is calculated using the following equation:

The fasting lipid profile provides more complete information about a child's cholesterol status and helps determine the approach to management (Fig. 75–8 (Figure Not Available)). Triglycerides must be less than 400?mg/dL to derive an accurate estimate of LDL cholesterol with this method. The average value from two evaluations is recommended because of the biologic and laboratory variability in lipid values. Children with average LDL cholesterol levels greater than 130?mg/dL are considered to have persistently high levels, whereas LDL cholesterol levels less than 110?mg/dL are considered acceptable. Levels between 110 and 130?mg/dL are borderline.

These recommendations have been criticized for several reasons. The screening algorithm is complicated to follow for the busy practitioner. Multiple surveys have shown that screening only those with a positive family history misses half or more of the hypercholesterolemic children. This problem is compounded by the fact that many adults do not know their cholesterol levels, as well as the difficulties in obtaining a complete family history. In addition, many parents who may be at risk for CHD are too young to have acquired clinical heart disease while their children are being evaluated; hence their children may not be identified as being at risk.

Those children with *triglyceride* levels greater than the 95th percentile can be a marker of some genetic forms of hyperlipidemia, even if the total cholesterol level is normal. Elevated triglycerides are also sometimes related to secondary hyperlipidemic or to the so-called “metabolic syndrome” (hyperlipidemic, insulin resistance, elevated blood pressure).

TREATMENT OF HYPERLIPIDEMIA

Dietary Management of Hyperlipidemia (see Fig. 75–8 (Figure Not Available)).

For hypercholesterolemic children (average LDL cholesterol > 110?mg/dL) older than 2 yr, dietary modification is the best initial intervention. Their daily food intake should provide no more than 30% of total calories as fat (approximately equally distributed among saturated, monounsaturated, and polyunsaturated fats), and no more than 100?mg cholesterol/1,000 calories (maximum 300?mg/24?hr) in such a modification program. This has become commonly referred to as the prudent, or Step I American Heart Association, diet. The American Academy of Pediatrics Committee on Nutrition confirms these recommendations and also suggests a lower limit for fat intake of no less than 20% of total calories. It is recommended that all family members older than 2 yr gradually adopt this diet to encourage optimal compliance and health promotion. The minimal goal for dietary intervention is to achieve an LDL cholesterol level less than 130?mg/dL, whereas the ideal goal is to lower it to less than 110?mg/dL. If these goals are not reached even after reinforcing the Step I diet, the Step II diet (< 7% calories as saturated fat and < 66?mg cholesterol/1,000 calories to a maximum of 200?mg/24?hr) should be considered.

When recommending dietary intervention, it is important to explain that the response to dietary management is variable and generally does not lower LDL cholesterol levels by more than 10–15%. Individuals commonly have unrealistic expectations about the cholesterol lowering associated with dietary management, which limits their compliance when the response is modest. Even if the initial response to dietary therapy is limited, the potential for adopting a lifelong healthy style of eating should have long-term benefit.

Dietary modification is safe in the treatment of hyperlipidemia in adults and children older than 2 yr. The Dietary Intervention Study for Children demonstrated the safety and efficacy of a low-fat diet for hypercholesterolemic children. However, it must be emphasized that these recommendations are meant only for children older than 2 yr.

Children younger than this placed on a similar or more restrictive diet, and older children placed on more restrictive diets by well-meaning caregivers, have demonstrated poor growth. Children younger than 2 yr require a relatively large amount of calories to maintain their rapid growth. Because of the higher caloric density of high-fat food, it is physically difficult for children younger than 2 yr to eat enough low-fat food to ensure normal growth. Furthermore, the higher fat intake may be necessary to help ensure an adequate supply of appropriate nutrients for the rapidly developing central nervous system. However, despite these concerns, the

Figure 75.4-8 (Figure Not Available) Flow chart of classification, education, and follow-up of children based on LDL cholesterol levels. (From Williams CL, Hayman LL, Daniels SR, et al: Cardiovascular health in childhood. *Circulation* 2002; 106:143–60.)

Special Turhu Coronary Risk Intervention Project has demonstrated that a lower fat diet supports normal growth in children as young as 6 mo old.

There should be proper supervision to ensure the appropriateness of any dietary modification in children, especially for young children. Because most pediatricians are unable to provide detailed guidance for such dietary modifications, referral to a trained pediatric dietitian is indicated. Before undertaking a screening program, the physician should ensure the availability of such referral. The growth and development of any child undergoing dietary intervention should be monitored, and a specific dietary evaluation should be completed if growth or development is altered. It is also important to explain to the child and family that hypercholesterolemia in childhood is only a risk factor and not an illness. Emphasis should be placed on the positive changes the child and the family can make to minimize the risk.

Other Dietary Factors.

Dietary fiber, especially soluble fiber, has a modest cholesterol-lowering effect in hypercholesterolemic individuals. However, high-fiber diets must be used with care in children to ensure adequate delivery of calories and nutrients. Monounsaturated fats lower LDL cholesterol levels while maintaining or even raising HDL cholesterol levels, in contrast to the lowering of LDL and HDL cholesterol levels commonly observed with a high polyunsaturated fat diet. *Trans*-fatty acids (partially hydrogenated vegetable oils), commonly found in processed foods and margarine, seem to raise LDL cholesterol levels. Vegetarian diets have a large and significant cholesterol-lowering effect associated with the substitution of vegetable protein for animal protein and the low fat and cholesterol content of the diet. Although many groups have demonstrated the safety of vegetarian diets for children, care must be taken to ensure the completeness of the diet for the growing child. Plant stanols and sterols have been shown to reduce LDL cholesterol levels modestly in adults if consumed three times per day and are commercially available as functional foods, although their safety and efficacy has not been demonstrated in children. Although fish oil and antioxidants have little, if any, effect on cholesterol levels, they have been reported to be associated with reduced risk of CHD by other mechanisms. (Fish oil is also used as a treatment for severe hypertriglyceridemia.) However, because these compounds are frequently administered in pharmacologic doses, in the absence of additional experience, their use in children should be discouraged. Dietary modification that increases intake of these nutrients can be considered. For example, encouraging appropriate fruit and vegetable intake will help optimize natural sources of antioxidants.

Other Factors Relating to Treatment.

Medical management of hypercholesterolemia should be viewed in the context of other lifestyle factors and conditions associated with risk for premature CHD,

such as lack of exercise and physical activity and excessive sedentary activity, cigarette smoking, hypertension, obesity, and diabetes. These should be evaluated, controlled, minimized, or eliminated as possible and appropriate. Children already having one risk factor for premature coronary heart disease, such as hyperlipidemia, should be actively treated to minimize any other risk factors. In addition, many of these risk factors are interlinked, and therefore minimizing one may help to ameliorate others (increasing exercise may decrease obesity, which helps to lower blood pressure, LDL cholesterol, and triglyceride levels and, potentially, the risk for type 2 dependent diabetes mellitus, while also helping raise HDL cholesterol levels).

Drug Therapy (see Fig. 75–8 (Figure Not Available)).

The Expert Panel on Treatment of Hyperlipidemia in Children recommended that drug therapy be considered in children aged 10 yr and older if, after an adequate trial (6 mo–1 yr) of diet therapy:

1. LDL cholesterol remains greater than 190?mg/dL.
2. LDL cholesterol remains greater than 160?mg/dL and (a) there is a positive family history of premature CHD (before 55 yr of age) or (b) two or more other risk factors are present in the child or adolescent after vigorous attempts have been made to control these risk factors (diabetes, hypertension, smoking, low HDL cholesterol, severe obesity, physical inactivity). It should be noted that the Adult Treatment Panel III of the National Cholesterol Education Program recommends an LDL cholesterol level less than 160?mg/dL for adults with one or fewer CHD risk factors. Primary disorders amenable to therapy are noted in Table 75–5 .

Bile acid sequestrants or “resins” (cholestyramine, colesevelam, or colestipol) are often the first-line pediatric drugs for the treatment of hypercholesterolemia in children. Bile acid sequestrants primarily reduce LDL cholesterol, and care should be taken in prescribing cholestyramine for patients with triglyceride levels greater than 300?mg/dL because they exacerbate hypertriglyceridemia. These nonabsorbable compounds interrupt the enterohepatic bile acid cycle by the binding of bile acids in the intestine and enhancing their excretion in the stool. This results

TABLE 75.4-5 -- Primary Lipoprotein Disorders Amenable to Treatment with Diet and Drug Therapy

Disorder	Mechanisms	Complications	Treatment*
Familial hypertriglyceridemia†	Decreased serum triglyceride removal resulting from decreased LPL activity Increased hepatic secretion of triglyceride-rich VLDL	Pancreatitis at triglyceride concentrations >2000?mg/dL (22.6?mmol/L); low risk of CAD	Diet and weight loss Fibrate Nicotinic acid n–3 fatty acids Oxandrolone
Familial combined hyperlipidemia†	Increased hepatic secretion of apolipoprotein B–containing VLDL and conversion to LDL Accumulation of VLDL, LDL, or both, depending on efficiency of their removal	CAD, PVD, stroke	Diet and weight loss Statin Nicotinic acid Fibrate‡
Remnant removal disease (familial dysbetalipoproteinemia)	Increased secretion of VLDL Impaired removal of remnant lipoproteins resulting from homozygosity (e2/e2) or heterozygosity (e2/e3 or e2/e4) for apolipoprotein E e2	PVD, CAD, stroke	Diet, weight loss Fibrate‡ Nicotinic acid Statin
Familial or polygenic hypercholesterolemia	Diminished LDL-receptor activity Defective apolipoprotein B that is poorly recognized by LDL receptor	CAD, occasionally PVD, stroke	Diet Statin Bile acid–binding resin Nicotinic acid
Familial hypoalphalipoproteinemia (low HDL syndrome)§	Diminished apolipoprotein AI formation, increased removal, increased CETP or hepatic lipase activity	CAD, PVD (may be associated with hypertriglyceridemia)	Exercise and weight loss Nicotinic acid Fibrate‡ Statin
L			
F			

** The treatments may be given alone or in combination; the primary treatment is listed first, followed by other treatments in decreasing order of importance.*
† Diabetes mellitus can greatly exacerbate the condition. The hyperlipidemia of diabetes is closest mechanistically to familial combined hyperlipidemia.
‡ Combined treatment with a fibrate and a statin can increase the risk of myopathy.
§ This disorder is characterized by low concentrations of HDL cholesterol.
LPL = lipoprotein lipase; VLDL = very-low-density lipoprotein; CAD = coronary artery disease; PVD = peripheral vascular disease; HDL = high-density lipoprotein; CETP = cholesterol-ester transfer protein.
From Knopp RH: Drug treatment of lipid disorders. N Engl J Med *1999;341:498–512.*

in shunting of hepatic cholesterol into bile acid synthesis and secondary upregulation of hepatic LDL receptors. As a result, there is increased uptake of LDL from the blood and reduction of LDL cholesterol levels. A 10–32% decrease in LDL cholesterol levels has been reported with cholestyramine therapy in children with familial hypercholesterolemia and familial combined hyperlipidemia (FCHL). However, reported long-term compliance has been poor and related to poor palatability of the medication and gastrointestinal disturbances, including nausea, bloating, and constipation. One packet or scoop contains 4?g of cholestyramine and 5?g of colestipol. The dose is titrated to the severity of hypercholesterolemia and tolerance of the side effects. Generally, resins are started at a dose of one-half packet or scoop twice a day before meals, and the dose is gradually increased over weeks as tolerated and necessary. Doses of three packets or scoops twice a day can be tolerated in some individuals. Colesevelam is available in tablets containing 625?mg. Four to 7 tablets per day is recommended.

The bile acid sequestrants are safe drugs that are not systemically absorbed. However, they are insoluble resins that must be suspended in liquid and are therefore often inconvenient and unpleasant to take. For this reason, some patients may prefer colesevelam tablets. In addition, bile acid sequestrants may bind other

drugs and interfere with their absorption, creating the need to take other medications 1?hr before or 4?hr after the bile acid sequestrants. Similarly, these resins may interfere with the absorption of fat-soluble vitamins, suggesting the need for multivitamin supplements (Table 75–6).

HMG-CoA reductase inhibitors (statins) have been used in children with severe hypercholesterolemia who cannot tolerate or have inadequate response to bile acid sequestrants. HMG-CoA reductase is the rate-limiting step in cholesterol biosynthesis, and inhibition of this enzyme decreases cholesterol synthesis and results in upregulation of hepatic LDL receptors. The Canadian Lovastatin in Children Study demonstrated a 21–36% decrease (dose response related) in LDL-cholesterol level in boys with familial hypercholesterolemia treated with 10–40?mg/day lovastatin. No serious side effects were noted over the 8-wk follow-up

TABLE 75.4-6 -- **Side Effects of Lipid-Lowering Drugs**

Drug and Site or Type of Effect	Effect
Statins	
Skin	Rash
Nervous system	Loss of concentration, sleep disturbance, headache, peripheral neuropathy
Liver	Hepatitis, loss of appetite, weight loss, and increases in serum aminotransferases to two to three times the upper limit of the normal range
Gastrointestinal tract	Abdominal pain, nausea, diarrhea
Muscles	Muscle pain or weakness, myositis (usually with serum creatine kinase >1000 U/L), rhabdomyolysis with renal failure
Immune system	Lupus-like syndrome (lovastatin, simvastatin, or fluvastatin)
Protein binding	Diminished binding of warfarin (lovastatin, simvastatin, fluvastatin)
Bile Acid–Binding Resins	
Gastrointestinal tract	Abdominal fullness, nausea, gas, constipation, hemorrhoids, anal fissure, activation of diverticulitis, diminished absorption of vitamin D in children
Liver	Mild serum aminotransferase elevations, which can be exacerbated by concomitant treatment with a statin
Metabolic system	Increases in serum triglycerides of approximately 10% (greater increases in patients with hypertriglyceridemia)
Electrolytes	Hyperchloremic acidosis in children and patients with renal failure (cholestyramine)
Drug interactions	Binding of warfarin, digoxin, thiazide diuretics, thyroxine, statins
Nicotinic Acid	
Skin	Flushing, dry skin, pruritus, ichthyosis, acanthosis nigricans
Eyes	Conjunctivitis, cystoid macular edema, retinal detachment
Respiratory tract	Nasal stuffiness
Heart	Supraventricular arrhythmias
Gastrointestinal tract	Heartburn, loose bowel movements or diarrhea
Liver	Mild increase in serum aminotransferases, hepatitis with nausea and fatigue
Muscles	Myositis
Metabolic system	Hyperglycemia (incidence, approximately 5%; higher in patients with diabetes), increase of 10% in serum uric acid
Fibrates	
Skin	Rash
Gastrointestinal tract	Stomach upset, abdominal pain (mainly gemfibrozil), cholesterol-saturated bile, increase of 1–2% in gallstone incidence
Genitourinary tract	Erectile dysfunction (mainly clofibrate)
Muscles	Myositis with impaired renal function
Plasma proteins	Interference with binding of warfarin, requiring reduction in the dose of warfarin by approximately 30%
Liver	Increased serum aminotransferases

F

period. These drugs are metabolized by the cytochrome P450 system, and drugs that inhibit or induce the system will raise or lower the drug level (and effect), respectively.

Potential side effects of statins include gastrointestinal upset, headache, sleep disturbance, fatigue, and muscle or joint pains (see Table 75–6). Severe myopathy and even rhabdomyolysis have been rarely reported with some HMG-CoA reductase inhibitors in adults. The risk of severe myopathy may be increased in patients taking certain other drugs such as erythromycin, antifungal agents, immunosuppressive agents, and fibric acid derivatives such as gemfibrozil and niacin. Liver transaminases should be monitored in patients taking statins, but significant (more than three times normal) elevation in transaminase levels is rare in children. However, because the long-term effects of statins remain uncertain, the risks and benefits of using them in children should be carefully considered. They should be used carefully in girls at risk of pregnancy because of the uncertainty of teratogenic

defects.

Nicotinic acid is also frequently used in adults; however, its side effects (flushing, gastrointestinal upset, hepatic toxicity) may preclude its use in children. The practicing pediatrician should consider referral of all children who may be candidates for drug therapy to a specialized pediatric lipid center.

Although drug therapy is used commonly to treat *hypertriglyceridemia* in adults, it is used much less commonly in children (see Table 75–5). The mainstay of therapy in children with hypertriglyceridemia is diet, exercise, and weight loss. In severe cases of hypertriglyceridemia in children with attendant medical complications, a lipid expert should complete a careful risk-benefit analysis considering the use of medication. There are no formal recommendations concerning the treatment of hypertriglyceridemia in children.

SAFETY CONSIDERATIONS.

Dietary intervention must be appropriately supervised to ensure that a complete and balanced diet is provided or available. In addition, the potential adverse psychosocial influence of being "labeled" should be considered. Children with heterozygous familial hypercholesterolemia (FH) attending a lipid clinic demonstrated no higher prevalence of psychosocial dysfunction, which could be potentially related to their being labeled "at risk," than control children. Furthermore, in one cholesterol screening program, the parents of hypercholesterolemic children reported better diets and improved perceptions of the children's health 1 yr after cholesterol screening was completed. This may be an effect of the families' active participation in reducing risk and improving health.

There are occasional reports in adults linking low or lowered cholesterol levels with depression, violent tendencies, accidents, and noncardiac illnesses, including some forms of cancer. These reports do not consistently demonstrate the same associations, and other studies present conflicting data (e.g., those reporting an association between high-fat diets and some forms of cancer). In addition, many of the cholesterol-lowering interventions use diet or drugs, or both, and thus negative consequences may be unrelated to the medication. However, the decreased overall mortality reported in well-conducted cholesterol lowering trials using HMG-CoA reductase inhibitors supports the overall safety and efficacy of lowering cholesterol. Data from other countries, in which mean cholesterol levels are lower than those in the United States, do not always support higher overall mortality related to lower cholesterol levels.

Secondary Hyperlipidemias.

Most of the hypertriglyceridemia and hypercholesterolemia seen in clinical practice in children is secondary to exogenous factors or underlying clinical disorders. Obesity, for example, is a major cause of elevations of plasma triglycerides, and the hypertriglyceridemia is frequently normalized after a return to desirable weight. Weight loss may also reduce cholesterol levels in overweight individuals.

Pediatric conditions associated with hyperlipidemia include hypothyroidism, diabetes mellitus, nephrotic syndrome, renal failure, storage diseases (glycogen storage disease, Tay-Sachs disease, Niemann-Pick disease), congenital biliary atresia and other causes of cholestasis, hepatitis, anorexia nervosa, and systemic lupus erythematosus. Excessive alcohol intake should be considered in teenagers. Oral contraceptives generally increase triglyceride levels, with varying effects on LDL and HDL cholesterol levels. Other drugs that raise triglyceride levels are 13-*cis*-retinoic acid (isotretinoin or Accutane), thiazide diuretics, steroids, HIV protease inhibitors, immunosuppressants, and some ß-adrenergic blocking agents. Treatment of the underlying condition or removal of the offending drug is usually the first approach to management of the patient with secondary hyperlipidemia. If the elevated lipid levels persist, however, consideration must be given to the possibility that the patient has an underlying primary form of HLP, and therapy appropriate to that condition should be initiated.

PRIMARY (GENETIC) DYSLIPIDEMIAS

One third of patients with their first myocardial infarction before the age of 50 yr in men and 60 yr in women have HLP; about one half of cases are due to an inherited disorder of lipoprotein metabolism. The Frederickson and Levy classification is useful as a guide to accurate diagnosis and effective treatment and is based on the type of lipoprotein that is elevated. For example, in type I, chylomicrons are increased; type IIa implies elevation of LDL; type IV, elevation of VLDL; type IIb, elevation of both LDL and VLDL; type III, elevation of chylomicron and VLDL remnants; and type V, elevation of VLDL and chylomicrons. These descriptive classifications do not imply specific genetic etiology; furthermore, as knowledge about the molecular basis of specific genetic defects in lipoprotein metabolism has grown (see Table 75–5), the classification has become less useful and may contribute to misunderstanding. However, because it is still quite prevalent in the literature, physicians need to be aware of the classification.

Disorders Associated with Hypercholesterolemia and Normal Triglycerides (<100?mg/dL)

Elevated cholesterol in the absence of elevated triglycerides generally indicates an elevation in LDL without a concomitant elevation in chylomicrons or VLDL. The LDL receptor plays a major role in regulating the plasma LDL cholesterol levels, and therefore the two major inherited causes of elevated LDL cholesterol both involve the LDL receptor pathway: mutations in the LDL receptor (FH) or in the receptor-binding region of apoB (familial defective apoB).

Familial Hypercholesterolemia.

FH is caused by mutations in the LDL receptor, which prevent its synthesis, reduce its appearance on the cell surface, or impair its ability to bind and internalize LDL. Elevated LDL cholesterol levels lead to the major complication of this condition: premature atherosclerotic cardiovascular disease. More than 600 different mutations in the LDL receptor have been described. There are five classes of mutations (null, transport defective, binding defective, internalization defective, and recycling

defective) that impair the receptor-mediated uptake of LDL from the circulation (see Fig. 75–7). FH is an autosomal codominant disorder; heterozygotes have hypercholesterolemia, but homozygotes have more severe hypercholesterolemia. One mutant LDL receptor allele results in the production of only about half of the normal number of LDL receptors, whereas two mutant alleles severely reduce or eliminate functional LDL receptors. Heterozygous and homozygous FH differ clinically in a number of important respects.

HETEROZYGOUS FAMILIAL HYPERCHOLESTEROLEMIA.

Heterozygous FH occurs in approximately 1/500 people worldwide, making it one of the most common single gene disorders. It is characterized by elevated total and LDL cholesterol levels with normal triglycerides and a family history of hypercholesterolemia or premature cardiovascular disease. The finding of tendon xanthomas is virtually diagnostic of FH, although absence of xanthomas does not exclude the diagnosis, especially in children with heterozygous FH in whom xanthomas are rare. Tendon xanthomas are easily recognized on the Achilles tendons, where they cause thickening and irregularity. Any child with suspected Achilles tendonitis, which may actually be developing Achilles tendon xanthomas, should have cholesterol screening to rule out FH. Another common location for tendon xanthomas is the digit extensor tendons on the dorsum of the hands. Premature corneal arcus is frequently seen in adults with heterozygous FH. There is no widely available definitive diagnostic test for heterozygous FH, which is diagnosed on clinical grounds.

Heterozygous FH is strongly associated with premature atherosclerotic cardiovascular disease, especially CHD. Children with heterozygous FH should be identified and treated to lower the LDL cholesterol and reduce the long-term risk of atherosclerotic CHD. *Treatment* should be initiated with a Step I diet, and followed by the Step II diet if needed. Dietary therapy reduces the LDL cholesterol but rarely normalizes it. Most patients with heterozygous FH require lipid-lowering drug therapy which has proven efficacy and safety in children (see Fig. 75–8 (Figure Not Available)).

HOMOZYGOUS FAMILIAL HYPERCHOLESTEROLEMIA.

Homozygous FH is caused by the inheritance of two mutant LDL receptor alleles that result in the production of little or no LDL receptors and a severe defect in the catabolism of LDL. Homozygous FH occurs in approximately 1 in 1 million persons worldwide and is a much more severe clinical disorder than heterozygous FH. Patients with homozygous FH are often classified into one of two groups based on the LDL cholesterol level and the amount of LDL receptor activity measured in their skin fibroblasts. “Receptor-negative” patients have less than 2% of normal LDL receptor activity and higher LDL cholesterol levels, whereas “receptor-defective” patients have 2–25% of normal LDL receptor activity and not as high LDL cholesterol levels. Receptor-defective patients have a better prognosis than do receptor-negative patients and sometimes have small responses to drug therapy. The clinical heterogeneity among homozygous FH patients is due to the significant genetic heterogeneity of the LDL receptor gene mutations.

Patients with homozygous FH often present in childhood with cutaneous xanthomas on the hands, wrists, elbows, knees, heels, or buttocks. Some patients with homozygous FH do not have cutaneous xanthomas but acquire tuberous or tendon xanthomas on the elbows, knees, or Achilles tendons as older children or adolescents. The absence of xanthomas in children does not exclude the diagnosis. Arcus cornea may be present to some degree. Total cholesterol levels are usually greater than 500?mg/dL and can be as high as 1200?mg/dL. The major complication of homozygous FH is accelerated atherosclerosis, which can result in clinical sequelae even in childhood. Homozygous FH children often have symptoms of vascular disease before puberty, but symptoms can be atypical or go unreported; sudden death is common. Untreated receptor-negative homozygous FH patients rarely survive beyond the 2nd decade; receptor-defective patients have a better prognosis but invariably experience clinical atherosclerotic vascular disease by age 30 yr and often much sooner.

A child with a total cholesterol level greater than 500?mg/dL and with relatively normal triglycerides, with or without cutaneous or tendon xanthomas, should be suspected of having homozygous FH. The biologic parents and other relatives should be tested for hypercholesterolemia. Obstructive liver disease and nephrotic syndrome should be excluded. The *diagnosis* is made on clinical grounds but can be confirmed in specialized

---

centers by obtaining a skin biopsy specimen and performing an assay of the LDL receptor activity on the skin fibroblasts. Patients with suspected homozygous FH should be referred to a specialized center for confirmation of the diagnosis and recommendations for therapy.

Drug therapy using a statin drug plus a bile acid sequestrant should be attempted. Receptor-defective patients may have a partial response to drug therapy. Liver transplantation is effective in decreasing LDL cholesterol levels but is associated with the substantial risks of surgery and long-term immunosuppression. The current *treatment* of choice for homozygous FH is LDL apheresis, which can promote regression of xanthomas and retard progression of atherosclerosis. The age at which LDL apheresis should be initiated is uncertain. Venous access is often problematic in young children, and central catheters are prone to infections, which are especially risky given the frequent aortic valvular and supravalvular flow disturbances. It is generally recommended that initiation of LDL apheresis be delayed until approximately 5 yr of age except when evidence of atherosclerotic vascular disease is present.

Five patients with homozygous FH were treated in a somatic gene therapy protocol involving ex vivo gene transfer of the LDL receptor gene into autologous hepatocytes with subsequent reimplantation. At 4 mo, all patients had evidence of LDL receptor transgene expression by liver biopsy. LDL cholesterol levels were decreased in two patients by 17% and 22% respectively, but LDL cholesterol levels in the other three patients were essentially unchanged.

Familial Defective Apolipoprotein B-100.

Familial defective apoB-100 (FDB) is characterized by elevated LDL cholesterol with normal triglycerides, possible tendon xanthomas, and increased risk of premature atherosclerotic cardiovascular disease. Clinically, it resembles heterozygous FH. In contrast to FH, FDB is caused by mutations in the receptor binding region of apoB-100, the ligand for the LDL receptor, which impairs its binding and delays the clearance of LDL from the blood. The most common mutation causing FDB is a substitution of glutamine for arginine at position 3500 in apoB-100. Other mutations have been reported that have a similar effect on apoB binding to the LDL receptor. FDB is a dominantly inherited disorder and occurs in approximately 1/700 people in Europe and North America. The apoB mutation can be detected in specialized laboratories. There is no compelling reason to make a specific molecular diagnosis because the clinical management of patients with FDB is similar to that of patients with heterozygous FH.

Sitosterolemia.

Sitosterolemia is a rare autosomal recessive disease associated with excess intestinal absorption and tissue accumulation of plant-derived sterols such as sitosterol and cholestanol. The molecular etiology of sitosterolemia is related to mutations in one of two different ATP-binding cassette proteins, ABCG5 and ABCG8. These intestinal and hepatic transporters presumably cooperate to limit intestinal absorption and promote biliary excretion of plant sterols and cholesterol.

Sitosterolemia can present with severe hypercholesterolemia, premature atherosclerosis, and tendon xanthomas similar to those seen in patients with homozygous or severe heterozygous FH. Sitosterolemia should be ruled out in patients presenting with these findings. Patients with sitosterolemia often benefit from treatment with bile acid sequestrants but do not benefit from HMG-CoA reductase inhibition. Patients suspected of having sitosterolemia should be referred to specialized centers for further evaluation and management.

Polygenic Hypercholesterolemia.

Most forms of hypercholesterolemia are not single gene disorders but rather due to a complex interaction of several genetic and environmental factors. Genetic differences in cholesterol absorption, cholesterol synthesis, or rates of bile acid synthesis may result in very different cholesterol levels in individuals challenged with a fat-rich diet. An elevated cholesterol level with triglyceride levels characterizes polygenic hypercholesterolemia. In polygenic hypercholesterolemia, LDL cholesterol levels usually are not as elevated as they are in heterozygous FH and FDB, and tendon xanthomas are not observed. About half of relatives with FCHL, heterozygous FH, and FDB have dyslipidemia, but fewer first-degree relatives of patients with polygenic hypercholesterolemia are hypercholesteremic. *Treatment* of polygenic hypercholesterolemia follows the same guidelines as the approach to any patient with hypercholesterolemia.

Disorders Associated with Hypercholesterolemia and Moderately Elevated Triglyceride Levels (100–1,000?mg/dL)

Although triglyceride levels more than 1,000?mg/dL are associated with acute pancreatitis (see later) the importance of elevated triglyceride levels in the 100–1,000?mg/dL range is primarily related to their potential association with the risk of the development of atherosclerotic CHD. The major primary causes of elevated triglycerides in the 100–1,000?mg/dL range are FCHL, familial dysbetalipoproteinemia (type III hyperlipidemia), and familial hypertriglyceridemia. It is important to differentiate among them because familial dysbetalipoproteinemia and FCHL are both definitely associated with increased risk of premature atherosclerosis, whereas familial hypertriglyceridemia may not be associated with increased risk.

Familial Combined Hyperlipidemia.

FCHL is a common primary lipid disorder, occurring in approximately 1/200 adults. It has been estimated that approximately 20% of patients with CHD younger than 60 yr have a form of FCHL. FCHL is characterized by a mixed dyslipidemia usually associated with moderately reduced HDL-C levels, elevated fasting triglycerides, and/or moderately elevated cholesterol. In this dominantly inherited syndrome, first-degree relatives on one side of the family frequently have hypertriglyceridemia, hypercholesterolemia, or combined elevations of both cholesterol and triglycerides; there is often a family history of premature CHD. The hyperlipidemia tends to be modest, and the lipoprotein abnormalities can change from time to time in the same affected individual. Xanthomas are not generally seen in patients with this disorder. Visceral abdominal obesity, glucose intolerance, hyperinsulinemia, and hypertension are frequently associated with FCHL but are not required for the diagnosis.

FCHL generally presents in adulthood but can be identified in children. In families with FCHL identified through an affected child, half the siblings younger than 20 yr of age have hyperlipidemia, compatible with dominant expression of the trait. A correlation between plasma triglyceride level and age and relative weight in affected children has also been observed, which suggests the gradual expression of hyperlipidemia in some children. It is estimated that at least 0.5% of all children have hyperlipidemia due to FCHL.

The molecular basis of FCHL is not known. Studies of lipoprotein metabolism in carefully selected individuals have indicated that overproduction of VLDL or LDL, or both, is a common metabolic basis of this condition. It has been suggested that a subset of patients with the FCHL phenotype may be heterozygous for lipoprotein lipase (LPL) deficiency, but LPL mutations are probably not a common cause of FCHL. A variant allele at a locus influencing apoB levels predicts FCHL in a large proportion of families ascertained through affected children; however, the function of this gene is unknown. There is evidence that FCHL is not linked to the apoB structural locus. It is likely that more than one genetic cause of the FCHL phenotype exists.

The *diagnosis* of FCHL is suggested by the presence of a mixed hyperlipidemia with fasting triglyceride and cholesterol levels both greater than the 90th percentile, especially if accompanied

by decreased HDL cholesterol levels and in the absence of secondary causes of

hyperlipidemia. Some affected family members may have only an elevated LDL-C or triglyceride level. The formal diagnosis of FCHL requires the presence of dyslipidemia in at least two first-degree relatives. Familial dysbetalipoproteinemia should be excluded with appropriate testing. The finding of an elevated apoB level (usually greater than the 90th percentile for age) suggests increased levels of “small dense LDL” and supports the diagnosis of FCHL. *Hyperapobetalipoproteinemia* has been used to describe the syndrome of elevated apoB with normal lipid levels and is probably a subset of FCHL.

The risk of premature heart disease for persons with FCHL is increased despite the fact that lipid levels in affected individuals may be only moderately elevated. Children in these families should therefore be identified, and initial dietary *treatment* should be aimed at controlling the hypercholesterolemia and hypertriglyceridemia using the Step I or Step II diet. Dietary modification in children with FCHL has generally demonstrated a 10–15% reduction in the LDL cholesterol level, although fewer than half of the treated children would be expected to have levels less than 130?mg/dL and even fewer would be expected to have levels of less than 110?mg/dL with dietary treatment. When dietary modification alone does not achieve desired results, drug therapy may be considered. Dietary changes resulting in lower LDL-C levels are also commonly associated with some rise in triglyceride levels; within reason, the primary focus remains on lowering LDL-C.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia).

Patients with familial dysbetalipoproteinemia usually present in adulthood with *clinical manifestations* that include distinctive xanthomas, premature atherosclerosis, or asymptomatic hyperlipidemia discovered on routine screening, although children may present with a “strange rash.” Two types of xanthomas can be seen in patients with familial dysbetalipoproteinemia. Tuberoeruptive xanthomas begin as clusters of small papules on the elbows, knees, or buttocks and can grow to the size of small grapes. Palmar xanthoma refers to orange-yellow discoloration in the creases of the palms and wrists. The pattern of hyperlipidemia can be a clue to the diagnosis of familial dysbetalipoproteinemia. Patients generally have both hypertriglyceridemia and hypercholesterolemia and, in contrast to most other lipid disorders, the cholesterol and triglyceride are often elevated to a relatively similar degree. In addition, the HDL cholesterol level is often relatively normal, in contrast to most hypertriglyceridemic conditions in which the HDL cholesterol level is usually reduced. The hyperlipidemia can be relatively mild or severe, depending on the presence of other metabolic conditions and unknown factors.

Familial dysbetalipoproteinemia is caused by mutations in the gene for apolipoprotein E (apoE). ApoE is present on chylomicron and VLDL remnants and mediates their removal from the plasma by binding to receptors in the liver. Defective apoE is impaired in its ability to bind to these receptors, resulting in accumulation of chylomicron and VLDL remnants in the plasma. The most common form of familial dysbetalipoproteinemia is related to a common polymorphism of apoE. The “normal” form of apoE is known as apoE3, but another form, apoE2, has an allele frequency of about 7%. The apoE2 protein, which differs from apoE3 by a single amino acid, does not bind to lipoprotein receptors adequately, resulting in defective removal of chylomicron and VLDL remnants. Homozygosity for the E2 allele (the E2/E2 genotype) is the most common cause of familial dysbetalipoproteinemia. However, most individuals with the apoE2/E2 genotype do not have familial dysbetalipoproteinemia; development of this disorder appears to require an additional factor. Some of these factors may include obesity, diabetes mellitus, hypothyroidism, renal disease, and alcohol use; most children with familial dysbetalipoproteinemia have one of these conditions in addition to the apoE2/E2 genotype. Many adults with familial dysbetalipoproteinemia do not have an obvious predisposing factor in addition to the E2/E2 genotype. Another common variant of apoE, known as apoE4, has an allele frequency of approximately 14% and is not associated with familial dysbetalipoproteinemia. Other rare mutations in apoE can also cause familial dysbetalipoproteinemia. These mutations generally result in the synthesis of an apoE protein that is severely defective in its ability to bind to lipoprotein receptors and can result in a more severe hyperlipidemia, which may be more likely to present in childhood. Often the inheritance of only one mutant allele is adequate to cause familial dysbetalipoproteinemia, leading to the term *dominant type III HLP*.

The traditional laboratory approach to *diagnosis* is to use lipoprotein electrophoresis, which demonstrates a broad ß-band owing to the presence of remnant lipoproteins. A second (and preferred) method is “ß quantification” in which plasma is subjected to ultracentrifugation to separate lipoproteins; this is available in specialized laboratories. Because this disorder is associated with increased numbers of VLDL remnants that are enriched in cholesterol relative to triglycerides, an elevated ratio of VLDL cholesterol to triglycerides of greater than 0.3 is confirmatory of the diagnosis. Finally, the apoE2/E2 pattern can be determined by using plasma protein methods (apoE phenotype) or DNA-based methods (apoE genotype). The finding of an apoE2/E2 pattern by phenotyping or genotyping in a patient with suspected familial dysbetalipoproteinemia confirms the diagnosis.

Familial dysbetalipoproteinemia is often sensitive to dietary *treatment*. Weight loss to a level appropriate for height, coupled with institution of the Step I diet, can often cause the lipid levels to return to normal. Discontinuance of alcohol can have a major impact on the dyslipidemia. There is little experience with drug treatment of this disorder in children, but adults with familial dysbetalipoproteinemia have been treated with fibric acid derivatives, nicotinic acid, and HMG-CoA reductase inhibitors, all of which tend to be effective in this disorder, although combination therapy is sometimes required.

Familial Hypertriglyceridemia.

Familial hypertriglyceridemia (FHTG) is characterized by moderately elevated triglycerides, usually in the absence of significant hypercholesterolemia. FHTG occurs in approximately 1/500 people and in contrast to FCHL frequently is not associated with premature CHD. Hypertriglyceridemia is often detected by a routine blood test. Triglyceride levels usually range from 250–1,000?mg/dL with normal to mildly increased cholesterol levels and HDL cholesterol levels that are usually decreased. FHTG is inherited as an autosomal dominant trait but is not usually expressed until adulthood. The molecular *etiology* is unknown. The metabolic basis of this disorder is probably heterogeneous but is likely to be related to impaired catabolism of triglyceride-rich lipoproteins. Increased production of VLDL by the liver has been observed in some patients with this phenotype. It is possible that VLDL or chylomicron overproduction, or both, may overload the normal catabolic processes and produce hypertriglyceridemia in some patients. It has been proposed that genetic overproduction of apoC-III could cause this syndrome, but this remains to be

proved. Increased dietary fat or simple carbohydrates, a sedentary lifestyle, obesity, insulin resistance, alcohol use, and estrogens can all exacerbate the hypertriglyceridemia.

The *diagnosis* is suggested by elevated triglyceride levels (>90th percentile) with normal or mildly increased cholesterol levels (<90th percentile). Hypertriglyceridemia in at least one first-degree relative is useful in making the diagnosis. It is important to consider and rule out secondary causes of the hypertriglyceridemia. In the differential diagnosis, both familial dysbetalipoproteinemia (type III HLP) and FCHL should

be considered. Relative to the triglyceride level, the total cholesterol level is usually lower in FHTG compared with familial dysbetalipoproteinemia and FCHL.

Children older than 2 yr can usually be *treated* adequately with weight control and use of the Step I diet. Occasionally, further modification of the carbohydrate to fat ratio may be required. Alcohol use should be discouraged. Diabetes mellitus should be aggressively controlled. Lipid-lowering drug therapy is generally not indicated in children, except in extreme cases. In such circumstances, fish oils may be an alternative to drug therapy, although the long-term safety in children is not known.

Hepatic Lipase Deficiency.

This is a rare autosomal recessive disorder. Hepatic lipase hydrolyzes triglycerides and phospholipids in VLDL remnants and IDL and promotes their conversion to LDL. Genetic deficiency of hepatic lipase impairs the metabolism of VLDL remnants and IDL and is characterized by a mixed hyperlipidemia and the accumulation of lipoprotein remnants in plasma. Hepatic lipase also metabolizes HDL lipids, so levels of HDL cholesterol are often slightly elevated in hepatic lipase deficiency. The *diagnosis* is suggested by a mixed hyperlipidemia with elevation in both triglyceride and cholesterol levels but an HDL cholesterol level that is normal or elevated rather than low. Familial dysbetalipoproteinemia should be excluded by apoE phenotyping or genotyping. Measurements of hepatic lipase can be made in postheparin plasma by specialized laboratories. The association of hepatic lipase deficiency with atherosclerosis is uncertain, but patients should be *treated* for their hyperlipidemia using an approach similar to that used for familial dysbetalipoproteinemia. Acquired (usually partial) defects in hepatic lipase can be seen in hypothyroidism, chronic renal insufficiency, and chronic liver disease.

Disorders Associated with Hypercholesterolemia and Severely Elevated Triglycerides (>1,000?mg/dL)

Fasting triglycerides greater than 1,000?mg/dL in children reflect severe hyperchylomicronemia and indicate an underlying genetic disorder. In some cases, this genetic factor is exacerbated by another medical condition or a hormonal or environmental factor. The major clinical complication of severe hypertriglyceridemia is acute pancreatitis, and initial treatment is focused on decreasing the triglycerides to less than 1,000?mg/dL to prevent this serious complication. Some patients with severe hypertriglyceridemia are at risk for premature atherosclerotic CHD and require more aggressive therapy even when the triglycerides have been decreased to less than the 1,000?mg/dL threshold.

Familial Chylomicronemia Syndrome: Lipoprotein Lipase Deficiency and Apolipoprotein C-II Deficiency.

The familial chylomicronemia syndrome is characterized by presentation in childhood with acute pancreatitis in the setting of triglyceride levels greater than 1,000?mg/dL. Recurrent abdominal pain is a common historical feature. Rarely, infants present with recurrent “colic.” The massive elevation of plasma triglycerides can be clinically silent and is sometimes discovered incidentally owing to the lipemic appearance of the blood. On physical examination, eruptive xanthomas (small papular lesions that occur in showers on the buttocks and back) may be seen. Lipemia retinalis (a pale appearance to the retinal veins) is a clue to the existence of severe hypertriglyceridemia; hepatosplenomegaly due to ingestion of chylomicrons by the reticuloendothelial system is often found. Premature atherosclerotic cardiovascular disease is not generally a feature of this disease.

Two different genetic defects can cause the familial chylomicronemia syndrome: LPL deficiency and apoC-II deficiency. The hydrolysis of triglycerides in chylomicrons requires the action of LPL in tissue capillary beds, and apoC-II is a required co-factor for the activation of LPL. Mutations in either the LPL gene or the apoC-II gene result in functional inability to hydrolyze triglycerides in chylomicrons and consequent hyperchylomicronemia. The disorder is autosomal recessive, and both alleles of the LPL or apoC-II gene must be affected. Therefore, the parents of children with this disorder generally have normal or near-normal triglyceride levels, and usually there is no family history of severe hyperlipidemia. Both are rare disorders, but of the two, LPL deficiency is more common (approximately 1/1 million persons) than apoC-II deficiency.

The *diagnosis* of the familial hyperchylomicronemia syndrome is usually made based on the clinical presentation and some key laboratory features. The plasma is lactescent and after overnight refrigeration, a cake of chylomicrons forms on the surface. Triglyceride levels are greater than 1,000?mg/dL and may be as high as 10,000?mg/dL or greater. Total cholesterol levels are also elevated because of the presence of cholesterol in chylomicrons. Lipoprotein electrophoresis demonstrates markedly elevated chylomicrons at the origin but is not essential for making the diagnosis. The diagnosis of LPL and apoC-II deficiency can be confirmed at specialized centers by the quantitation of LPL activity in the plasma after intravenous heparin injection (post-heparin lipolytic activity). Patients with suspected familial chylomicronemia syndrome should be referred to a specialized lipid center for diagnosis and management.

The mainstay of *treatment* for familial chylomicronemia syndrome is restriction of total dietary fat. Consultation with a registered dietitian familiar with this disorder is essential. Caloric supplementation with medium-chain triglycerides, which are absorbed directly into the portal vein and therefore do not promote chylomicron formation, can be useful. If dietary fat restriction alone is not successful, some patients may respond to a cautious trial of fish oils. For patients with apoC-II deficiency, an attack of acute pancreatitis that fails to resolve can be treated with infusion of fresh frozen plasma to provide an exogenous source of apoC-II in an attempt to clear severe hypertriglyceridemia and promote resolution of the

pancreatitis.

Type V Hyperlipoproteinemia (HLP).

Type V HLP is common in adults but rare in children. The *diagnosis* of type V HLP is made in a patient with fasting triglyceride levels greater than 1,000?mg/dL (fasting hyperchylomicronemia) who does not have LPL or apoC-II deficiency. Type V HLP is also associated with acute pancreatitis, which can be the initial presentation of this syndrome and is the major rationale for aggressive treatment. Most but not all patients with type V HLP have a family history of hypertriglyceridemia. Type II diabetes mellitus or glucose intolerance frequently accompanies type V hyperlipidemia, but type V hyperlipidemia also occurs in individuals with normal glucose tolerance. Some patients with nephrotic syndrome can acquire severe hypertriglyceridemia. Estrogen-containing therapy can exacerbate moderate hypertriglyceridemia and lead to a more severe type V hyperlipidemia, as can heavy alcohol use. Treatment with isotretinoin or etretinate sometimes causes severe hypertriglyceridemia.

The *treatment* of type V hyperlipidemia is first targeted to decreasing triglycerides to reduce the risk of pancreatitis, followed by further lipid lowering depending on the presence of CHD or other risk factors for cardiovascular disease. Patients taking medications that exacerbate hypertriglyceridemia may need to discontinue them if triglyceride levels are greater than 1,000?mg/dL. Diabetes mellitus should be controlled. Patients should be referred to a registered dietitian for dietary counseling. Dietary management includes restriction of total fat as well as simple sugars in the diet. Alcohol should be avoided. Regular aerobic exercise can have a significant impact on triglyceride levels and should be actively encouraged. If the patient is overweight, weight loss can help to decrease triglyceride levels. When fasting triglyceride levels remain greater than 1,000?mg/dL despite institution of appropriate dietary and lifestyle measures and control of secondary causes, drug therapy should be considered

---

to decrease the risk of acute pancreatitis. None of the agents used in the treatment of hypertriglyceridemia is approved for use in children.

Disorders of High-Density Lipoprotein Metabolism.

HDL cholesterol levels are inversely associated with CHD independent of total and LDL cholesterol levels. Although the National Cholesterol Education Program recommends that all adults older than 20 yr should be screened for total cholesterol and HDL cholesterol levels as part of a full fasting lipid profile, it is recommended that only children with a positive family history of premature heart disease have a complete lipid profile including HDL cholesterol. Many causes of low HDL cholesterol are secondary to other factors. Cigarette smoking, obesity, physical inactivity, type II diabetes mellitus, end-stage renal disease, hypertriglyceridemia from any cause, and the use of ß-blockers, thiazide diuretics, androgens, progestins, and probucol can all reduce HDL cholesterol levels. A low-fat diet can also result in a low level of HDL cholesterol; the low HDL is not considered to be associated with an increased risk of CHD, because persons who eat low-fat diets are at substantially reduced risk of premature CHD. Several rare genetic disorders can also be associated with low HDL cholesterol levels.

Familial APOA-I Deficiency and Structural APOA-I Mutations.

Complete genetic deficiency of apoA-I due to deletions of the apoA-I gene or nonsense mutations that prevent the biosynthesis of apoA-I protein may result in virtually absent plasma HDL. These extremely rare patients acquire corneal opacities and sometimes cutaneous or planar xanthomas. The risk of premature cardiovascular disease in patients with apoA-I deficiency is increased, but onset of CHD symptoms in these kindreds has varied from the 3rd to 7th decades. In contrast, mutations of apoA-1 that permit the secretion of a mutant apoA-1 protein are not generally associated with premature coronary artery disease. Interestingly, a few apoA-I mutations have been described in association with systemic amyloidosis, and the mutant apoA-1 has been found as a component of the amyloid plaque.

Tangier Disease.

ABCA1 is a cellular protein that facilitates the efflux of cellular cholesterol to lipid-poor apoA-1. Tangier disease is a rare disorder caused by mutations in *ABCA1*, resulting in a cellular defect in efflux of cholesterol, and particularly affects macrophages and related cells. It is associated with cholesterol accumulation in the reticuloendothelial system, resulting in hepatosplenomegaly, intestinal mucosal abnormalities, and pathognomonic enlarged, orange tonsils. Intermittent peripheral neuropathy can also be seen from cholesterol accumulation in Schwann cells. Tangier disease is frequently diagnosed in childhood because of the finding of enlarged orange-colored tonsils. Patients with Tangier disease have HDL cholesterol levels less than 5?mg/dL and extremely low levels of apoA-I, owing to markedly accelerated HDL catabolism.

Tangier disease is associated with some increased risk of premature atherosclerotic disease, but this risk is not proportional to the markedly decreased HDL cholesterol and apoA-I levels. Tangier disease is an autosomal codominant disease; obligate heterozygotes have moderately reduced HDL cholesterol levels but no evidence of reticuloendothelial cholesterol accumulation. The risk of premature atherosclerosis in obligate heterozygotes is uncertain but may also be increased.

Familial Lecithin:Cholesterol Acyltransferase Deficiency.

Unesterified cholesterol effluxed from cells to HDL is esterified by lecithin:cholesterol acyltransferase (LCAT). Two general types of genetic LCAT deficiency have been described in humans: complete deficiency (classic LCAT deficiency) and partial deficiency (fish-eye disease). Both types are extremely rare. Progressive corneal opacification in young adulthood is characteristic of both types; in addition, complete (classic) LCAT deficiency (but not partial deficiency) is characterized by anemia and progressive proteinuria and renal insufficiency in young adulthood. Both types are characterized by very low plasma levels of HDL cholesterol (usually <10?mg/dL) and variable hypertriglyceridemia. The diagnosis of LCAT deficiency is rarely made in childhood and is suspected when there is corneal opacification, renal insufficiency, or an incidentally discovered very low HDL cholesterol level. The diagnosis can be

confirmed in specialized laboratories by quantitation of LCAT and cholesterol esterification activity in the plasma. Remarkably, despite the extremely low levels of HDL cholesterol and apoA-I, there is no apparent increased risk of premature atherosclerotic cardiovascular disease in either complete or partial LCAT deficiency.

Primary Hypoalphalipoproteinemia.

The most common inherited form of low HDL is termed *primary* or *familial hypoalphalipoproteinemia*. It is defined as an HDL cholesterol level less than the 10th percentile in the setting of relatively normal cholesterol and triglyceride levels, no apparent secondary causes of low HDL, and no clinical signs of LCAT deficiency or Tangier disease. This syndrome is often referred to as “isolated low HDL.” A family history of low HDL cholesterol facilitates the diagnosis of an inherited condition, which usually follows the pattern of an autosomal dominant trait. The genetic etiology of this syndrome is unknown, although the metabolic cause appears to be primarily accelerated catabolism of HDL and its apolipoproteins. The direct relationship of primary hypoalphalipoproteinemia to premature coronary disease is uncertain and may depend on the specific nature of the gene defect or metabolic cause of the low HDL cholesterol level.

CONDITIONS ASSOCIATED WITH LOW CHOLESTEROL LEVELS

Abetalipoproteinemia.

This is a rare autosomal recessive disease characterized by fat malabsorption, spinocerebellar degeneration, and pigmented retinopathy. The biochemical hallmark of this disease is the strikingly abnormal plasma lipid and lipoprotein profile. Total cholesterol and triglyceride levels are extremely low; there are no detectable plasma chylomicrons, VLDL, or LDL; and apoB is absent from the plasma. This disease is caused by mutations in the gene for the microsomal triglyceride transfer protein, which mediates the intracellular transport of membrane-associated lipids in the intestine and liver and is necessary for the normal formation of chylomicrons in the enterocyte and VLDL in the hepatocyte.

The most prominent and debilitating *clinical manifestations* of abetalipoproteinemia are neurologic and usually begin in the 2nd decade. The first sign of disease is usually the loss of deep tendon reflexes, followed by decreased distal lower extremity vibratory and proprioceptive senses and cerebellar signs such as dysmetria, ataxia, and spastic gait. The clinical outcome is variable, but the result in untreated patients is often severe ataxia and spasticity by the 3rd or 4th decade. These severe effects on the central nervous system are the ultimate cause of death in most patients and often occur by the 5th decade or earlier. Patients with abetalipoproteinemia also acquire a progressive pigmented retinopathy. The presence of both spinocerebellar degeneration and pigmented retinopathy in this disease may result in a misdiagnosis of Friedreich ataxia. The first ophthalmic symptoms are decreased night and color vision. Daytime visual acuity usually deteriorates inexorably to virtual blindness by the 4th decade.

The majority of the clinical symptoms of abetalipoproteinemia are the result of defects in absorption and transport of fat-soluble vitamins, especially vitamin E. Vitamin E is transported from the intestine to the liver, then “repackaged” in the liver and incorporated into the assembling VLDL particle by a specific protein termed the *tocopherol binding protein*. In the circulation, VLDL is converted to LDL, and vitamin E is transported by LDL to peripheral tissues and delivered to cells via the LDL receptor. Patients with abetalipoproteinemia are markedly deficient in

vitamin E. Vitamin E metabolism is greatly altered in patients with abetalipoproteinemia because the plasma transport of vitamin E requires hepatic secretion of apoB-containing lipoproteins. Most of the major clinical symptoms, especially those of the nervous system and retina, are primarily caused by vitamin E deficiency. This concept is supported by the fact that other diseases involving vitamin E deficiency, such as cholestasis and isolated vitamin E deficiency, are characterized by similar symptoms and pathologic changes. Patients with suspected abetalipoproteinemia should be referred to specialized centers for confirmation of the diagnosis and institution of appropriate therapy.

Obligate heterozygotes (parents of patients with abetalipoproteinemia) have no symptoms and no evidence of reduced plasma lipids. Thus, family studies are important in distinguishing abetalipoproteinemia from clinically similar homozygous hypobetalipoproteinemia in which obligate heterozygotes have decreased LDL cholesterol and apoB levels.

Familial Hypobetalipoproteinemia.

Familial hypobetalipoproteinemia, in contrast to abetalipoproteinemia, is autosomal codominant. Heterozygotes have levels of LDL cholesterol and apoB that are approximately one half of normal or less, whereas homozygotes have very low or no plasma apoB. Heterozygous familial hypobetalipoproteinemia is not associated with symptoms, whereas some homozygous patients have symptoms that are similar to those in abetalipoproteinemia patients. The gene defect in this disorder resides in most or all cases within the apoB gene itself. Many are nonsense mutations resulting in a truncated apoB protein; at least 25 such mutations have been described to date. One patient who was initially described as having “normotriglyceridemic abetalipoproteinemia” has subsequently been demonstrated to be homozygous for a truncated apoB and therefore has homozygous hypobetalipoproteinemia.

Clinically, heterozygous hypobetalipoproteinemia is associated with LDL cholesterol levels in the 40–80?mg/dL range, is not associated with clinical sequelae, and requires no specific therapy. However, patients with homozygous hypobetalipoproteinemia have markedly reduced to absent LDL cholesterol and apoB levels and may be at risk for many of the sequelae seen in abetalipoproteinemia. Such patients should therefore be referred to specialized centers for confirmation of the diagnosis and institution of appropriate therapy.

Chylomicron Retention Disease.

Chylomicron retention disease, or Anderson disease, is associated with the selective inability to secrete apoB from intestinal enterocytes, resulting in fat malabsorption

and sometimes neurologic disease similar to that seen in abetalipoproteinemia and homozygous hypobetalipoproteinemia. In contrast to these two disorders, apoB-100 can be detected in the plasma of patients with chylomicron retention disease, because hepatic VLDL secretion is normal. The molecular defect is unknown but appears to be distinct from both the microsomal triglyceride transfer protein and apoB genes.

Smith-Lemli-Opitz Syndrome.

This syndrome is a recessive genetic disorder characterized by neurologic developmental defects including microcephaly, hypotonia, and severe mental retardation as well as micrognathia, widespread ears, cataracts, epicanthal folds, blepharoptosis, and syndactyly. Additional features are noted in Boxes 75–3 and 75–4 . The prevalence of homozygotes is about 1/20,000 births, and the estimated gene carrier frequency is 1–2%. Smith-Lemli-Opitz syndrome is caused by defects in the gene encoding the enzyme 7-dehydrocholesterol-d-7-reductase, which is required to convert 7-dehydrocholesterol to cholesterol. Patients have very low plasma cholesterol levels, and the neurologic defects are presumed to be caused by limited cholesterol availability within the central nervous system for neural growth. Cholesterol therapy (50?mg/kg/day) results in improvement in behavioral abnormalities and

improves postnatal growth. Because high concentrations of the cholesterol precursor 7-dehydrocholesterol may be toxic, therapy with simvastatin, an inhibitor of the cholesterol synthetic pathway, may provide additional benefit.

ADDITIONAL DISORDERS OF CHOLESTEROL SYNTHESIS

Mevalonic Aciduria.

This malformation syndrome is caused by a deficiency of mevalonate kinase and results in massive excretion of mevalonic acid, an intermediate in cholesterol synthesis (see Chapter 74.6). Patients manifest mental retardation, hypotonia, low-set posteriorly rotated ears, blue sclerae, cataracts, dolichocephaly, hepatosplenomegaly, long eyelashes, and an inflammatory syndrome associated with elevated IgD levels. This periodic fever, hyperimmunoglobulin D syndrome is associated with rash, fever, diarrhea, arthralgias, and an elevated erythrocyte sedimentation rate, which is treated with corticosteroids.

The serum cholesterol level is low or normal.

Conradi-Hünermann Syndrome.

These patients have normal or low serum cholesterol levels and malformations consisting of rhizomelic chondrodysplasia. There may be a defect in gene locus for 3ß-hydroxysteroid ?^{8} , ?^{7} isomerase. The disorder is inherited as an X-linked dominant (affecting only females; lethal to male fetuses) or an autosomal recessive disorder. Patients with the X-linked disease demonstrate rhizomelic limbs, asymmetrically shortened ichthyosis, alopecia, and cataracts (see Chapters 75.2 and 648).

CHILD Syndrome.

This X-linked dominant disorder affects females (possibly lethal to male fetuses) and is manifest by a unilateral exfoliative erythematous dermatitis (psoriasis-like) with facial sparing, unilateral hypomelia ipsilateral to the dermatosis, punctate vertebrae, epiphyseal calcification, and airway cartilage calcification. CHILD is an acronym for congenital hemidysplasia, ichthyosiform erythroderma, and limb defects. There may also be unilateral renal aplasia and congenital heart disease.

Desmosterolosis.

Deficiency of 3ß-hydroxysterol-?^{24} -reductase results in this syndrome, manifest by congenital heart defects, ambiguous genitalia in males, rhizomelic limbs, macrocephaly, gingival nodules, and thickened alveolar ridges.

SELECTED GENETIC DISORDERS OF INTRACELLULAR CHOLESTEROL METABOLISM

Cerebrotendinous Xanthomatosis.

This is an autosomal recessive disorder caused by mutations in the gene for sterol 27-hydroxylase, a mitochondrial enzyme involved in the normal biosynthesis of bile acids in the liver. As a result of the deficiency in sterol 27-hydroxylase, bile acid intermediates are shunted into the synthesis of cholestanol, which then accumulates in multiple tissues. If untreated, patients acquire cataracts, tendon xanthomas, and progressive disease of the central and peripheral nervous system in the 2nd decade of life. Early diagnosis is crucial, because treatment with chenodeoxycholic acid reduces plasma cholestanol levels and prevents the progression of clinical symptoms.

Cholesterol Ester Storage Disease and Wolman Disease.

Cholesterol ester storage disease (CESD) or Wolman disease is an autosomal recessive disorder caused by mutations in the gene for lysosomal acid lipase, a lysosomal enzyme required for hydrolysis of cholesteryl esters and triglycerides in the lysosome. See Chapter 75.4 .

Niemann-Pick C Disease.

The Niemann-Pick group of diseases includes autosomal recessive diseases characterized by accumulation of cholesterol and sphingomyelin in tissues, especially the liver, reticuloendothelial system, and central nervous system. Niemann-Pick A and B are described in Chapters 75.4 and 592.1 . Niemann-Pick C disease is a disorder of intracellular cholesterol transport for which the molecular cause has been established. Niemann-Pick C is characterized by hepatosplenomegaly and progressive neurologic disease, often resulting in severe disability and death by the 2nd decade.

75.5 Lipidoses

Margaret M. McGovern
Robert J. Desnick

The lysosomal lipid storage diseases are diverse disorders each due to an inherited deficiency of a lysosomal hydrolase leading to the lysosomal accumulation of the enzyme's particular substrate (Table 75–7). With the exception of Wolman disease (cholesterol ester storage disease), the lipid substrates share a common structure that includes a ceramide backbone (2-*N*-acyl-sphingosine) from which the various sphingolipids are derived by substitution of hexoses, phosphorylcholine, or one or more sialic acid residues on the terminal hydroxyl group of the ceramide molecule. The pathway of sphingolipid metabolism in nervous tissue (Fig. 75–9) and in visceral organs (Fig. 75–10) is known; each catabolic step has a genetically determined metabolic defect. Because sphingolipids are essential components of all cell membranes, the inability to degrade these substances and their subsequent accumulation results in the physiologic and morphologic alterations and characteristic clinical manifestations of the lipid storage disorders (see Table 75–7). Progressive lysosomal accumulation of glycosphingolipids in the central nervous system leads to neurodegeneration, whereas storage in visceral cells can lead to organomegaly, skeletal abnormalities, pulmonary infiltration, and other manifestations. The storage of a substrate in a specific tissue is dependent on its normal distribution in the body.

Diagnostic assays for the identification of affected individuals rely on the measurement of the specific enzymatic activity in isolated leukocytes or cultured fibroblasts. For most disorders, carrier identification and prenatal diagnosis are available; a specific diagnosis is essential to permit genetic counseling of the family. The characterization of the genes that encode the specific enzymes required for sphingolipid metabolism permit the development of therapeutic options, such as recombinant enzyme replacement therapy, as well as the potential of gene

Figure 75.5-9 Pathways in the metabolism of sphingolipids found in nervous tissues. The name of the enzyme catalyzing each reaction is given with the name of the substrate acted on. Inborn errors are depicted as bars crossing the reaction arrows, and the name of the associated defect or defects is given within the nearest box. The gangliosides are named according to the nomenclature of Svennerholm. Anomeric configurations are given only at the largest starting a compound. gal = galactose; glc = glucose; NAcgal = *N*-acetyl-galactosamine; NANA = *N*-acetyl-neuraminic acid; PC = phosphorylcholine.

therapy. Identification of specific disease-causing mutations improves diagnosis, prenatal detection, and carrier identification. For some disorders (e.g., Gaucher disease), it has been possible to make genotype-phenotype correlations that predict disease severity and allow more precise genetic counseling. Inheritance is autosomal recessive except for X-linked Fabry disease.

GM_1 Gangliosidosis.

GM_1 gangliosidosis most frequently presents in early infancy (type 1 disease) but has been described in patients with a juvenile onset (type 2). Both are autosomal

recessive traits; each results from the deficient activity of ß-galactosidase, a lysosomal enzyme encoded by a gene on chromosome 3 (3p21.33). Although the disorder is characterized by pathologic accumulation of GM_1 gangliosides in the lysosomes of both neural and visceral cells, GM_1 ganglioside accumulation is most marked in the brain. In addition, keratan sulfate, a mucopolysaccharide, accumulates in liver and is excreted in the urine of patients with GM_1 gangliosidosis. The ß-galactosidase gene has been isolated and sequenced, and mutations causing either type 1 or type 2 disease have been identified.

The *clinical manifestations* of the infantile form of GM_1 gangliosidosis (type 1 disease) may be evident in the newborn as hepatosplenomegaly, edema, and skin eruptions (angiokeratomata). It most frequently presents within the first 6 mo of life with developmental delay followed by progressive psychomotor retardation and the onset of tonic-clonic seizures. A typical facies characterized by low-set ears, frontal bossing, a depressed nasal bridge, and abnormally long philtrum is also evident. Up to 50% of patients have a macular cherry-red spot. Hepatosplenomegaly and skeletal abnormalities similar to those of the mucopolysaccharidoses, including anterior beaking of the vertebrae, enlargement of the sella turcica, and thickening of the calvarium, are present. By the end of the 1st yr of life, most patients are blind and deaf, with severe neurologic impairment characterized by decerebrate rigidity. Death usually occurs by 3–4 yr of age. The juvenile-onset form of GM_1 gangliosidosis (type 2) is clinically distinct, with a variable age at onset. Affected patients present primarily with neurologic symptoms including ataxia, dysarthria, mental retardation, and spasticity. Deterioration is slow; patients may survive through the 4th decade of life. These patients lack the visceral involvement, facial abnormalities, and

Figure 75.5-10 Pathways in the degradation of sphingolipids found in visceral organs and red or white blood cells. See also the legend for Figure 75–9 . fuc = fucose; NAcglc = *N*-acetylglucosamine.

skeletal features seen in type 1 disease. There is no specific *treatment* for either form of GM_1 gangliosidosis.

The *diagnosis* of GM_1 gangliosidosis should be suspected in infants with typical clinical features and is confirmed by the demonstration of the deficiency of ß-galactosidase activity in peripheral leukocytes or cultured skin fibroblasts. Other disorders that share some of the features of the GM_1 gangliosidoses include Hurler disease (mucopolysaccharidosis type I), I-cell disease, and Niemann-Pick disease (NPD) type A, which can each be distinguished by the demonstration of their specific enzymatic deficiencies. Carriers of the disorder are detected by the measurement of the enzymatic activity in white blood cells or cultured skin fibroblasts; prenatal diagnosis is accomplished by determination of the enzymatic activity in cultured aminocytes or chorionic villi.

The GM_2 Gangliosidoses.

The GM_2 gangliosidoses include *Tay-Sachs* disease and *Sandhoff disease*; each results from the deficiency of ß-hexosaminidase activity and the lysosomal accumulation of GM_2 gangliosides, particularly in the central nervous system. Both disorders have been classified into infantile-, juvenile-, and adult-onset forms based on the age at onset and clinical features. ß-Hexosaminidase occurs as two isozymes: ß-hexosaminidase A, which is composed of one a and one ß subunit, and ß-hexosaminidase B, which has two ß subunits. ß-hexosaminidase deficiency results from mutations in the a subunit and causes Tay-Sachs disease, whereas mutations in the ß-subunit gene result in the deficiency of both ß-hexosaminidases A and B and cause Sandhoff disease. Both are autosomal recessive traits, with Tay-Sachs disease having a predilection in the Ashkenazi Jewish population, where the carrier frequency is about 1/25.

More than 50 mutations have been identified; most are associated with the infantile forms of disease. Three mutations account for more than 98% of mutant alleles among Ashkenazi Jewish carriers of Tay-Sachs disease, including one allele associated with the adult-onset form. Mutations that cause the subacute or chronic forms result in enzyme proteins with residual enzymatic activities, the levels of which correlate with the severity of the disease.

Patients with the infantile form of Tay-Sachs disease have *clinical manifestations* in infancy of loss of motor skills, increased startle reaction, and macular pallor and retinal cherry-red spots (see Table 75–7). Affected infants usually develop normally until 4–5 mo of age when decreased eye contact and an exaggerated startle response to noise (hyperacusis) are noted. Macrocephaly, not associated with hydrocephalus, may develop. In the 2nd yr of life, seizures requiring anticonvulsant therapy develop. Neurodegeneration is relentless, with death occurring by the age of 4 or 5 yr. The juvenile-onset form initially presents with ataxia and dysarthria and may not be associated with a macular cherry-red spot.

The *clinical manifestations* of Sandhoff disease are similar to those for Tay-Sachs disease. However, infants with Sandhoff disease have hepatosplenomegaly, cardiac involvement, and mild bony abnormalities. The juvenile form of this disorder presents as ataxia, dysarthria, and mental deterioration, but without visceral enlargement or a macular cherry-red spot. There is no *treatment* available for Tay-Sachs disease or Sandhoff disease.

The *diagnosis* of infantile Tay-Sachs disease and Sandhoff disease is usually suspected in an infant with neurologic features and a cherry-red spot. Definitive diagnosis is by determination of the level of ß-hexosaminidases A and B in isolated blood leukocytes. The two disorders are distinguished by the enzymatic assay, because in Tay-Sachs disease only the ß-hexosaminidase A isozyme is deficient, whereas in Sandhoff disease both the ß-hexosaminidase A and B isozymes are deficient. Future at-risk pregnancies for both disorders can be monitored by prenatal

diagnosis by amniocentesis or chorionic villus sampling. Identification of carriers within families is also possible by ß-hexosaminidases A and B determination. Indeed, for Tay-Sachs disease, carrier screening of all couples in whom at least one member is of Ashkenazi Jewish descent is recommended before the initiation of pregnancy to identify couples at risk. These studies can be conducted by the determination of the level of ß-hexosaminidase A activity in peripheral leukocytes or plasma. Molecular studies to identify the exact molecular defect in enzymatically identified carriers should also be performed to permit more specific identification of carriers in the family, and for at-risk couples to allow prenatal diagnosis by both enzymatic and genotype determinations. The incidence of Tay-Sachs disease has been markedly reduced since the introduction of carrier screening programs in the Ashkenazi Jewish population.

Gaucher Disease.

This disease is a multisystemic lipidosis characterized by hematologic problems, organomegaly, and skeletal involvement, the latter usually manifested as bone pain and pathologic fractures (see Table 75–7). It is the most common lysosomal storage disease and the most prevalent genetic defect among Ashkenazi Jews. There are three clinical subtypes delineated by the absence or presence and progression of neurologic manifestations: Type 1 or the adult, non-neuronopathic form; type 2, the infantile or acute neuronopathic form; and type 3, the juvenile or Norrbotten form. All are autosomal recessive traits. Type 1, which accounts for 99% of cases, has a striking predilection for Ashkenazi Jews, with an incidence of about 1/1,000 and a carrier frequency of 1/18.

Gaucher disease results from the deficient activity of the lysosomal hydrolase, acid ß-glucosidase, which is encoded by a gene located on chromosome 1 q21-q31. The enzymatic defect results in the accumulation of undegraded glycolipid substrates, particularly glucosylceramide, in cells of the reticuloendothelial system. This progressive deposition results in infiltration of the bone marrow, progressive hepatosplenomegaly, and skeletal complications. Four mutations—N370S, L444P, 84insG, and IVS2—account for about 95% of mutant alleles among Ashkenazi Jewish patients, permitting screening for this disorder in this population. Genotype-phenotype correlations have been noted, providing the molecular basis for the clinical heterogeneity seen in Gaucher disease type 1, which has a wide range of severity and age at onset. Patients who are homozygous for the N370S mutation tend to have later onset, with a more indolent course than patients with one copy of N370S and another common allele.

Clinical manifestations of type 1 Gaucher disease have a variable age at onset, from early childhood to late adulthood, with most symptomatic patients presenting by adolescence. At presentation, patients may bruise easily owing to thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated liver function test results, splenomegaly, and bone pain. Occasional patients have pulmonary involvement at the time of presentation. Patients presenting in the 1st decade frequently are not Jewish and have growth retardation and a more malignant course. Other patients may be discovered fortuitously during evaluation for other conditions or as part of routine examinations; these patients may have a milder or even a benign course. In symptomatic patients, splenomegaly is progressive and can become massive. Most patients develop radiologic evidence of skeletal involvement, including an Erlenmeyer flask deformity of the distal femur. Clinically apparent bony involvement, which occurs in more than 20% of patients, can present as bone pain or pathologic fractures. Lytic lesions can develop in the long bones, including the femur, ribs, and pelvis; osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis or bruising and is frequently overlooked until other symptoms become apparent. With the exception of the severely growth-retarded child, who may experience developmental delay secondary to the effects of chronic disease, development and intelligence are normal.

The pathologic hallmark of Gaucher disease is the Gaucher cell in the reticuloendothelial system, particularly in the bone marrow (Fig. 75–11). These cells, which are 20 to 100?µm in diameter, have a characteristic wrinkled paper appearance resulting from the presence of intracytoplasmic substrate inclusions. The cytoplasm of the Gaucher cell reacts strongly positively with the periodic acid-Schiff stain. The presence of this cell in bone marrow and tissue specimens is highly suggestive of Gaucher disease, although it also may be found in patients with granulocytic leukemia and myeloma.

Gaucher disease type 2 is much less common and does not have an ethnic predilection. It is characterized by a rapid neurodegenerative course with extensive visceral involvement and death within the first 2 yr of life. It presents in infancy with increased tone, strabismus, and organomegaly. Failure to thrive and stridor caused by laryngospasm are typical. After a several-year period of psychomotor regression, death occurs

Figure 75.5-11 Cells from a spleen of a patient with Gaucher disease. A characteristic spleen cell is shown engorged with glucocerebroside.

---

secondary to respiratory compromise. Gaucher disease type 3 presents as clinical manifestations that are intermediate to those seen in types 1 and 2, with presentation in childhood and death by age 10–15 yr. It has a predilection for the Swedish Norrbottnian population, where the incidence is 1/50,000. Neurologic involvement is present but occurs later and with decreased severity compared with type 2 disease. Type 3 disease is further classified as types 3a and 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Gaucher disease should be considered in the *differential diagnosis* of patients with unexplained organomegaly, who bruise easily, have bone pain, or have a combination of these conditions. Bone marrow examination usually reveals the presence of Gaucher cells. All suspected diagnoses should be confirmed by determination of the acid ß-glucosidase activity in isolated leukocytes or cultured fibroblasts. The identification of carriers can be achieved by enzymatic assay, with confirmation of results by molecular testing in most Jewish families. Testing should be offered to all family members, keeping in mind that heterogeneity, even among members of the same kindred, can be so great that nonsymptomatic affected individuals may be diagnosed. Prenatal diagnosis is available by determination of

enzyme activity in chorionic villi or cultured amniotic fluid cells.

Treatment of patients with Gaucher disease type 1 includes enzyme replacement therapy, with recombinant acid ß-glucosidase (imiglucerase). Most extraskeletal symptoms (organomegaly, hematologic indices) are reversed by an initial debulking dose of enzyme (60?IU/kg) administered by intravenous infusion every other week. Monthly maintenance enzyme replacement improves bone structure, decreases bone pain, and induces compensatory growth in affected children. A small number of patients have undergone bone marrow transplantation, which is curative but results in significant morbidity and mortality from the procedure, making the selection of appropriate candidates limited. Efforts are also under way to develop gene therapy for type 1 disease.

Niemann-Pick Disease (NPD).

The original description of NPD was what is now known as type A NPD, a fatal disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by 2–3 yr of age. Type B is a non-neuronopathic form observed in children and adults. Type C is a neuronopathic form that results from defective cholesterol transport. All the subtypes are inherited as autosomal recessive traits and display variable clinical features (see Table 75–7).

NPD types A and B result from the deficient activity of acid sphingomyelinase, a lysosomal enzyme encoded by a gene on chromosome 11 (11p15.1-p15.4). The enzymatic defect results in the pathologic accumulation of sphingomyelin, a ceramide phospholipid, and other lipids in the monocyte-macrophage system, the primary pathologic site. The progressive deposition of sphingomyelin in the central nervous system results in the neurodegenerative course seen in type A, and in non-neural tissue in the systemic disease manifestations of type B, including progressive lung disease in some patients. The acid sphingomyelinase gene is sequenced, and a variety of mutations that cause types A and B NPD are known.

The *clinical manifestations* and course of type A NPD is uniform and is characterized by a normal appearance at birth (although the newborn period is sometimes complicated by prolonged jaundice). Hepatosplenomegaly, moderate lymphadenopathy, and psychomotor retardation are evident by 6 mo of age, followed by neurodevelopmental regression. With advancing age, the loss of motor function and the deterioration of intellectual capabilities are progressively debilitating; and in later stages, spasticity and rigidity are evident. Affected infants lose contact with their environment. In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most are diagnosed in infancy or childhood when enlargement of the liver or spleen, or both, is detected during a routine physical examination. At diagnosis, type B NPD patients usually have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on the chest radiograph. Pulmonary symptoms are not usual until adulthood. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth, the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations.

In some type B patients, decreased pulmonary diffusion caused by alveolar infiltration becomes evident in late childhood or early adulthood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by 15–20 yr of age. Such patients have low P_{O_2} values and dyspnea on exertion. Life-threatening bronchopneumonias may occur, and cor pulmonale has been described. Severely affected patients may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia due to secondary hypersplenism may require partial or complete splenectomy; this should be avoided if possible because splenectomy frequently causes progression of pulmonary disease, which can be life threatening. In general, type B patients do not have neurologic involvement and have a normal IQ. Some patients with type B disease have cherry red maculae or haloes and subtle neurologic symptoms (peripheral neuropathy).

Type C NPD patients often present with prolonged neonatal jaundice, appear normal for 1–2 yr, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that in patients with types A or B NPD, and they may survive into adulthood. The underlying biochemical defect in type C patients is an abnormality in cholesterol transport, leading to the accumulation of sphingomyelin and cholesterol in their lysosomes and a secondary partial reduction in acid sphingomyelinase activity (see Chapter 75.3).

In type B NPD patients, splenomegaly is usually the first manifestation detected. The splenic enlargement is noted in early childhood; however, in very mild disease, the enlargement may be subtle and detection may be delayed until adolescence or adulthood. The presence of the characteristic NPD cells in the bone marrow aspirates supports the diagnosis of type B NPD. However, patients with type C NPD also have extensive infiltration of NPD cells in the bone marrow and, thus, all suspected cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity level in peripheral leukocytes, cultured fibroblasts, or lymphoblasts, or a combination of these cells. Patients with types A and B NPD have markedly decreased levels (1–10%), whereas patients with type C NPD have somewhat decreased acid sphingomyelinase activities. The enzymatic identification of NPD carriers is problematic. However, in families in which the specific molecular lesion has been identified, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B NPD can be made reliably by the measurement of acid sphingomyelinase activity in cultured amniocytes or chorionic villi; molecular analysis of fetal cells can provide the specific diagnosis or serve as a confirmatory test. The clinical diagnosis of type C NPD can be supported by the demonstration of filipin stain positivity in cultured fibroblasts and/or by identifying a specific mutation in the NPC gene.

There is no specific *treatment* for NPD. Orthotopic liver transplantation in an infant with type A disease and amniotic cell transplantation in several type B NPD patients have been

attempted with little or no success. Bone marrow transplantation in one type B NPD

patient was successful in reducing the spleen and liver volumes, the sphingomyelin content in the liver, the number of NPD cells in the marrow, and the radiologic infiltration of the lungs. However, this patient died 3 mo after transplantation. Lung transplantation has not been performed in any severely compromised type B patient. Future prospects for treatment of type B disease include enzyme replacement and gene therapy. Treatment of types A and C disease is presently precluded by the severe neurologic involvement.

Fabry Disease.

This condition is an inborn error of glycosphingolipid metabolism characterized by angiokeratomas (telangiectatic skin lesions), hypohidrosis, corneal and lenticular opacities, acroparesthesias, and vascular disease of the kidney, heart, and/or brain (see Table 75–7). The disease is an X-linked recessive trait that is manifested in affected males and has an estimated prevalence of about 1/50,000 males. Atypical variants with residual a-galactosidase A activity may be asymptomatic or have late-onset, mild disease manifestations primarily limited to the heart. Heterozygous females are usually asymptomatic or exhibit mild manifestations.

The disease results from the deficient activity of a-galactosidase A, a lysosomal enzyme encoded by a gene located on the long arm of the X chromosome (Xq22). The enzymatic defect leads to the systemic accumulation of neutral glycosphingolipids, primarily globotriaosylceramide, particularly in the plasma and lysosomes of vascular endothelial and smooth muscle cells. The progressive vascular glycosphingolipid deposition in affected males results in ischemia and infarction, leading to the major disease manifestations. Affected males who have blood group B or AB have a more severe disease course because the blood group B substances also accumulate, as they are normally degraded by a-galactosidase A. The cDNA and genomic sequences encoding a-galactosidase A have identified over 200 different mutations in the a-galactosidase A gene that are responsible for this lysosomal storage disease, including amino acid substitutions, gene rearrangements, and mRNA splicing defects.

Clinical manifestations include angiokeratomas, which usually occur in childhood and may lead to early diagnosis. They increase in size and number with age and range from barely visible to several millimeters in diameter. The lesions are punctate, dark red to blue-black, and flat or slightly raised. They do not blanch with pressure, and the larger ones may show slight hyperkeratosis. Characteristically, the lesions are most dense between the umbilicus and knees, in the “bathing trunk area,” but may occur anywhere, including the oral mucosa. The hips, thighs, buttocks, umbilicus, lower abdomen, scrotum, and glans penis are common sites, and there is a tendency toward symmetry. Variants without skin lesions have been described. Sweating is usually decreased or absent. Corneal opacities and characteristic lenticular lesions, observed under slit lamp examination, are present in affected males as well as in about 70% of asymptomatic heterozygotes. Conjunctival and retinal vascular tortuosity are common and result from the systemic vascular involvement.

Pain is the most debilitating symptom in childhood and adolescence. Fabry crises, lasting from minutes to several days, consist of agonizing, burning pain in the hands and feet and proximal extremities and are usually associated with exercise, fatigue, or fever, or a combination of these factors. These painful acroparesthesias usually become less frequent in the 3rd and 4th decades of life, although in some men they may become more frequent and severe. Attacks of abdominal or flank pain may simulate appendicitis or renal colic.

The major morbid symptoms result from the progressive involvement of the vascular system. Early in the course of the disease, casts, red cells, and lipid inclusions with characteristic birefringent “Maltese crosses” appear in the urinary sediment. Proteinuria, isosthenuria, and gradual deterioration of renal function and development of azotemia occur in the 2nd through 4th decades. Cardiovascular findings may include hypertension, left ventricular hypertrophy, anginal chest pain, myocardial ischemia or infarction, and heart failure. Mitral insufficiency is the most common valvular lesion. Abnormal electrocardiographic and echocardiographic findings are common. Cerebrovascular manifestations result from multifocal small vessel involvement. Other features may include chronic bronchitis and dyspnea, lymphedema of the legs without hypoproteinemia, episodic diarrhea, osteoporosis, retarded growth, and delayed puberty. Death most often results from uremia or vascular disease of the heart or brain. Before hemodialysis or renal transplantation, the mean age at death for affected men was 41 yr. Atypical male variants with residual a-galactosidase A activity who are asymptomatic or mildly affected have been described whose manifestations include late-onset, isolated cardiac disease and proteinuria but normal renal function for age. These patients do not have the early classic manifestations. These “cardiac variants” have cardiomegaly, usually involving the left ventricular wall and interventricular septum, and electrocardiographic abnormalities consistent with cardiomyopathy. Others have had hypertrophic cardiomyopathy and/or myocardial infarction.

The *diagnosis* in classically affected males is most readily made from the history of painful acroparesthesias, hypohidrosis, the presence of characteristic skin lesions, and the observation of the characteristic corneal opacities and lenticular lesions. The disorder is often misdiagnosed as rheumatic fever, erythromelalgia, or neurosis. The skin lesions must be differentiated from the benign angiokeratomas of the scrotum (Fordyce disease) or from angiokeratoma circumscriptum. Angiokeratomas identical to those of Fabry disease have been reported in fucosidosis, aspartylglycosaminuria, late-onset GM_1 gangliosidosis, galactosialidosis, a-*N*-acetylgalactosaminidase deficiency, and sialidosis. The diagnosis of the mild cardiac variants should be considered in individuals who present with left ventricular hypertrophy or cardiomyopathy, or both. The diagnosis of classic and variant patients is confirmed biochemically by the demonstration of markedly decreased a-galactosidase A activity in plasma, isolated leukocytes, or cultured fibroblasts or lymphoblasts.

Heterozygous females may have corneal opacities, isolated skin lesions, and intermediate activities of a-galactosidase A in plasma or cells. Rare female heterozygotes may have manifestations as severe as those in affected males. However, at-risk females in families affected by Fabry disease who are asymptomatic should be optimally diagnosed by the direct analysis of their family's specific mutation. Prenatal detection of affected males can be accomplished by the demonstration of deficient a-galactosidase A activity or the family's specific gene mutation in chorionic villi obtained in the 1st trimester or in cultured amniocytes obtained by amniocentesis in the 2nd trimester of pregnancy.

Treatment for Fabry disease was once nonspecific and limited to supportive care, which included the use of phenytoin and/or carbamazepine to decrease the

frequency and severity of the chronic acroparesthesias and the periodic crises of excruciating pain. Renal transplantation and long-term hemodialysis also have become life-saving procedures for patients with renal failure. Recombinant a-galactosidase is a safe and effective enzyme replacement therapy for Fabry disease. The enzyme is well tolerated. Treatment results in very significant clearance of globotriaosylceramide from the vascular endothelial cells of the kidney, heart, and skin, as well as the cells of the glomerulus.

Fucosidosis.

Fucosidosis is a rare, autosomal recessive disorder caused by the deficient activity of a-fucosidase and the accumulation of

fucose-containing glycosphingolipids, glycoproteins, and oligosaccharides in the lysosomes of the liver, brain, and other organs (see Table 75–7). The a-fucosidase gene is on chromosome 1 (1p24), and specific mutations are known. Although the disorder is panethnic, most affected patients are from Italy and the United States. There is wide variability in the clinical phenotype, with the most severely affected patients presenting in the 1st yr of life with developmental delay and somatic features similar to those of the mucopolysaccharidoses. These features include frontal bossing, hepatosplenomegaly, coarse facial features, and macroglossia. The central nervous system storage results in a relentless neurodegenerative course with death in childhood. Patients with milder disease have angiokeratomas and longer survival. No specific therapy exists for the disorder, which can be diagnosed by the demonstration of deficient a-fucosidase activity in peripheral leukocytes or cultured fibroblasts. Carrier identification studies and prenatal diagnosis are possible by determination of the enzymatic activity.

Schindler Disease.

This disease is an autosomal recessive neurodegenerative disorder that results from the deficient activity of a-*N*-acetylgalactosaminidase and the accumulation of sialylated and asialoglycopeptides and oligosaccharides (see Table 75–7). The gene for the enzyme is mapped to chromosome 22 (22q13.1-13.2). The disease is clinically heterogeneous, and two major phenotypes have been identified. Type 1 disease is an infantile-onset neuroaxonal dystrophy. Affected infants have normal development for the first 9–15 mo of life followed by a rapid neurodegenerative course that results in severe psychomotor retardation, cortical blindness, and frequent myoclonic seizures. Type II disease is characterized by a variable age at onset, mild retardation, and angiokeratomas. There is no specific therapy for either form of the disorder. The diagnosis is by demonstration of the enzymatic deficiency in leukocytes or cultured skin fibroblasts

Metachromatic Leukodystrophy.

Metachromatic leukodystrophy (MLD) is an autosomal recessive white matter disease caused by a deficiency of arylsulfatase A (ASA), which is required for the hydrolysis of sulfated glycosphingolipids. An additional form of MLD is caused by a deficiency of a sphingolipid activator protein (SAP1), a protein required for the formation of the substrate-enzyme complex. The deficiency of this enzymatic activity results in the white matter storage of sulfated glycosphingolipids, which leads to demyelination and a neurodegenerative course. The ASA gene is on chromosome 22 (22q13.31qter); specific mutations are known to fall into two groups that correlate with disease severity.

The *clinical manifestations* of the late infantile form of MLD, which is most common, usually presents between 12–18 mo of age as irritability, inability to walk, and hyperextension of the knee, causing genu recurvatum. Deep tendon reflexes are diminished or absent. Gradual muscle wasting, weakness, and hypotonia become evident and lead to a debilitated state. As the disease progresses, nystagmus, myoclonic seizures, optic atrophy, and quadriparesis appear, with death in the 1st decade of life (see Table 75–7). The juvenile form of the disorder has a more indolent course with onset that may occur as late as 20 yr of age. This form of the disease presents as gait disturbances, mental deterioration, urinary incontinence, and emotional difficulties. The adult form, which presents after the 2nd decade, is similar to the juvenile form in its clinical manifestations, although emotional difficulties and psychosis are more prominent features. Dementia, seizures, diminished reflexes, and optic atrophy also occur in both the juvenile and adult forms. The pathologic hallmark of MLD is the deposition of metachromatic bodies, which stain strongly positive with periodic acid–Schiff and alcian blue, in the white matter of the brain. Neuronal inclusions may be seen in the midbrain, pons, medulla, retina, and spinal cord; demyelination occurs in the peripheral nervous system. Attempts to treat patients with MLD with bone marrow transplantation have resulted in normal enzymatic levels in peripheral blood, but no clear evidence for clinical efficacy in terms of the neurologic course; supportive care remains the primary intervention.

The *diagnosis* of MLD should be suspected in patients with the clinical features of leukodystrophy. Decreased nerve conduction velocities, increased cerebrospinal fluid protein, metachromatic deposits in sampled segments of sural nerve, and metachromatic granules in urinary sediment are all suggestive of MLD. Confirmation of the diagnosis is based on the demonstration of the reduced activity of ASA in leukocytes or cultured skin fibroblasts. Sphingolipid activator protein deficiency is diagnosed by measuring the concentration of SAP1 in cultured fibroblasts using a specific antibody to the protein. Carrier detection and prenatal diagnosis is available for all forms of the disorder.

Multiple Sulfatase Deficiency.

This is an autosomal recessive disorder that results from the deficiency of three enzymatic activities: arylsulfatases A, B, and C. Sulfatides, mucopolysaccharides, steroid sulfates, and gangliosides accumulate in the cerebral cortex and visceral tissues, resulting in a clinical phenotype with features of leukodystrophy as well as those of the mucopolysaccharidoses. Severe ichthyosis also may occur. Carrier testing and prenatal diagnosis by measurement of the enzymatic activities can be performed. There is no specific treatment for multiple sulfatase deficiency other than supportive care.

Krabbe Disease.

This condition, also called *globoid cell leukodystrophy*, is an autosomal recessive fatal disorder of infancy. It results from the deficiency of the enzymatic activity of galactocerebrosidase and the white matter accumulation of galactosylceramide, which is normally found almost exclusively in the myelin sheath. The galactocerebrosidase gene is on chromosome 14 (14q31), and specific disease-causing mutations are known. The infantile form of Krabbe disease is rapidly progressive and patients present in early infancy with irritability, seizures, and hypertonia (see Table 75–7). Optic atrophy is evident in the 1st yr of life, and mental development is severely impaired. As the disease progresses, optic atrophy and severe developmental delay become apparent; affected children exhibit opisthotonos and die before 3 yr of age. A second, late infantile form of Krabbe disease also exists and patients present after the age of 2 yr. Affected individuals have a disease course similar to that of the early infantile form. Bone marrow transplantation has been attempted in several patients with later-onset disease but without significant results. There is no available therapy. The diagnosis of Krabbe disease relies on the demonstration of the specific enzymatic deficiency in white blood cells or cultured skin fibroblasts. Carrier identification and prenatal diagnosis are available.

Farber Disease.

This is an autosomal recessive disorder that results from the deficiency of the lysosomal enzyme, ceramidase, and the accumulation of ceramide in various tissues, especially the joints. Symptoms can begin as early as the 1st yr of life with painful joint swelling and nodule formation (Fig. 75–12), which is sometimes diagnosed as rheumatoid arthritis. As the disease progresses, nodule or granulomatous formation on the vocal cords can lead to hoarseness and breathing difficulties; failure to thrive is common. In some patients, moderate central nervous system dysfunction is present (see Table 75–7). Patients may die of recurrent pneumonias in their teens; there is currently no specific therapy. The diagnosis of this disorder should be suspected in patients who have nodule formation over the joints but no other findings of rheumatoid arthritis. In such patients, ceramidase activity should be determined in cultured skin fibroblasts or white blood cells. Carrier detection and prenatal diagnosis are available.

Wolman Disease and Cholesterol Ester Disease (CESD).

Wolman disease and cholesterol ester storage disease are autosomal recessive lysosomal storage diseases that result from the deficiency of

Figure 75.5-12 A forearm of an 18-mo-old girl with Farber disease. Note the painful joint swelling and the nodule formation. The infant was suspected of having rheumatoid arthritis.

acid lipase and the accumulation of cholesterol esters and triglycerides in histiocytic foam cells of most visceral organs. The gene for lysosomal acid lipase is on chromosome 10 (10q24-q25). Wolman disease is the more severe clinical phenotype and is a fatal disorder of infancy. The clinical features of the disease become apparent in the 1st wk of life and include failure to thrive, relentless vomiting, abdominal distention, steatorrhea, and hepatosplenomegaly (see Table 75–7). There usually is hyperlipidemia. Hepatic dysfunction and fibrosis may occur. Calcification of the adrenal glands is pathognomonic for the disorder. Death usually occurs within 6 mo.

Cholesterol ester storage disease is a less severe disorder that may not be diagnosed until adulthood. Hepatomegaly can be the only detectable abnormality, but affected individuals are at significant risk for premature atherosclerosis. Adrenal calcification is not a feature.

Diagnosis and carrier identification are based on measuring acid lipase activity in leukocytes or cultured skin fibroblasts. Prenatal diagnosis depends on measuring decreased enzyme levels in cultured chorionic villi or amniocytes. There is no specific therapy available for either disorder, although the use of pharmacologic agents to suppress cholesterol synthesis in combination with cholestyramine and diet modification has been used in patients with cholesterol ester storage disease (see Chapter 75.3).

75.6 Mucolipidoses

Margaret M. McGovern
Robert J. Desnick

I-cell disease (mucolipidosis II, ML-II) and pseudo-Hurler polydystrophy (mucolipidosis III, ML-III) are biochemically related, rare autosomal recessive disorders that share some clinical features with Hurler syndrome. These diseases result from the abnormal transport of newly synthesized lysosomal enzymes that are normally targeted to the lysosome by the presence of mannose-6-phosphate residues and are recognized by specific lysosomal membrane receptors. These mannose-6-phosphate recognition markers are synthesized in a two-step reaction that occurs in the Golgi apparatus and is mediated by two enzymatic activities. The enzyme that catalyzes the first step, UDP-*N*-acetylglucosamine:lysosomal enzymes *N*-acetylglucosamine-1-phosphotransferase, is defective in both ML-II and ML-III. This enzyme deficiency results in abnormal targeting of the lysosomal enzymes that are then secreted into the extracellular matrix. Because the lysosomal enzymes require the acidic medium of the lysosome to function, patients with this defect accumulate a variety of different substrates due to the cellular deficiency of all lysosomal enzymes. The diagnosis of ML-II and ML-III can be made by the determination of the serum lysosomal enzymatic activities, which are elevated, or by the demonstration of reduced enzymatic levels in cultured skin fibroblasts. Direct measurement of the phosphotransferase activity is possible. Prenatal diagnosis and carrier identification studies are available for both disorders by measurement of lysosomal enzymatic activities in cultured cells.

I-Cell Disease.

I-cell disease shares many of the clinical manifestations of Hurler syndrome, although there is no mucopolysacchariduria and the presentation is earlier (see Table 75–7). Some patients have clinical features evident at birth, including coarse facial features, craniofacial abnormalities, restricted joint movement, and hypotonia. Nonimmune hydrops may be present in the fetus. The remainder of patients present in the 1st yr with severe psychomotor retardation, coarse facial features, and skeletal manifestations that include kyphoscoliosis and a lumbar gibbus. Patients also may have congenital dislocation of the hips, inguinal hernias, and gingival hypertrophy. Progressive, severe psychomotor retardation leads to death in early childhood. No *treatment* is available.

Pseudo-Hurler Polydystrophy.

Pseudo-Hurler polydystrophy is a less severe disorder, with later onset and survival

to adulthood reported. Affected children may present around the age of 4 or 5 yr with joint stiffness and short stature. Progressive destruction of the hip joints and moderate dysostosis multiplex are evident. Radiographic evidence of low iliac wings, flattening of the proximal femoral epiphyses with valgus deformity of the femoral head, and hypoplasia of the anterior third of the lumbar vertebrae are characteristic findings. Ophthalmic findings include corneal clouding, retinopathy, and astigmatism; visual complaints are uncommon (see Table 75–7). Some patients have learning disabilities or mental retardation. Treatment, which should include orthopedic care, is symptomatic.

Chapter 76 - Defects in Metabolism of Carbohydrates

Carbohydrate synthesis and degradation provide the energy required for most metabolic processes. The important carbohydrates include three monosaccharides—glucose, galactose, and fructose—and a polysaccharide, glycogen. The relevant biochemical pathways of these carbohydrates are shown in Figure 76–1 (Figure Not Available) . Glucose is the principal substrate of energy metabolism in humans. A continuous source of glucose from dietary intake, gluconeogenesis, and degradation of glycogen maintains normal blood glucose levels. Metabolism of glucose generates adenosine triphosphate (ATP) via glycolysis (conversion of glucose

Figure 76-1 (Figure Not Available) Pathway related to glycogen storage diseases and galactose and fructose disorders. Nonstandard abbreviations are as follows: GS_a , active glycogen synthetase; GS_b , inactive glycogen synthetase; P_a , active phosphorylase; P_b , inactive phosphorylase; P_a P, phosphorylase a phosphatase; P_b K_a , active phosphorylase b kinase; P_b K_b , inactive phosphorylase b kinase; G, glycogenin, the primer protein for glycogen synthesis. (Modified from AR Beaudet: Glycogen storage disease. In Isselbacher KJ, et al [editors]: *Harrison's Principles of Internal Medicine*, 13th ed. New York, McGraw-Hill, 1994. Reproduced with permission of The McGraw-Hill Companies.)

or glycogen to pyruvate) or mitochondrial oxidative phosphorylation (conversion of pyruvate to carbon dioxide and water), or both. Dietary sources of glucose come from ingesting polysaccharides, primarily starch, and disaccharides, including lactose, maltose, and sucrose. Oral intake of glucose is intermittent and unreliable. Glucose made de novo (gluconeogenesis) contributes to maintaining the euglycemic state, but this process requires time to be active. The breakdown of hepatic glycogen provides the rapid release of glucose, which maintains a constant blood glucose concentration. Glycogen is also the primary stored energy source in muscle, providing glucose for muscle activity during exercise. Galactose and fructose are monosaccharides that provide fuel for cellular metabolism; their role is less significant than that of glucose. Galactose is derived from lactose (galactose + glucose), which is found in milk and milk products. Galactose is an important energy source in infants, but it is first metabolized to glucose. Galactose (exogenous or endogenously synthesized from glucose) is also an important

component for certain glycolipids, glycoproteins, and glycosaminoglycans. The two

dietary sources of fructose are sucrose (fructose + glucose) and fructose itself, which is found in fruits, vegetables, and honey.

Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues, hence the name *glycogen storage disease* (Table 76–1). Defects in gluconeogenesis or the glycolytic pathway, including galactose and fructose metabolism, do not result in an accumulation of glycogen (see Table 76–1). The defects in pyruvate metabolism in the pathway of the conversion of pyruvate to carbon dioxide and water via mitochondrial oxidative phosphorylation are more often associated with lactic acidosis and some tissue glycogen accumulation.

Clinical manifestations of disorders of carbohydrate metabolism differ markedly. The symptoms range from harmless to lethal. Dietary therapy has been effective in many of the carbohydrate disorders. All genes responsible for the inherited defects of carbohydrate metabolism are cloned and mutations identified.

76.1 Glycogen Storage Diseases

Yuan-Tsong Chen

Glycogen storage diseases are inherited disorders affecting glycogen metabolism. Virtually all enzymes involved in the synthesis or degradation of glycogen cause some type of glycogen storage disease (see Fig. 76–1 (Figure Not Available)). The glycogen found in these disorders is abnormal in quantity or quality or both. Glycogen storage diseases are categorized by numeric type in accordance with the chronologic order in which these enzymatic defects were identified. This numeric classification is still widely used, at least up to number VII. The glycogen storage diseases can also be classified by organ involvement and clinical manifestations into liver and muscle glycogenoses (see Table 76–1).

There are more than 12 forms of glycogenoses. Glucose-6-phosphatase deficiency (type I), lysosomal acid a-glucosidase deficiency (type II), debrancher deficiency (type III), and liver phosphorylase kinase deficiency (type IX) are the most common that present in early childhood; myophosphorylase deficiency (type V, McArdle disease) is the most common in adults. The frequency of all forms of glycogen storage disease is approximately 1/20,000 live births.

LIVER GLYCOGENOSES

The glycogen storage diseases that principally affect the liver include glucose-6-phosphatase deficiency (type I), debranching enzyme deficiency (type III), branching enzyme deficiency (type IV), liver phosphorylase deficiency (type VI), phosphorylase kinase deficiency (type IX, formerly type VIa), glycogen synthetase deficiency, and glucose transporter-2 defect. Because hepatic carbohydrate metabolism is responsible for plasma glucose homeostasis, this group of disorders typically causes fasting hypoglycemia and hepatomegaly. Some (type III, type IV) are also associated with cirrhosis. Other organs may also be involved and may manifest as renal dysfunction in type I and myopathy in types III and IV as well as in some rare forms of phosphorylase kinase deficiency.

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, Von Gierke Disease)

Type I glycogen storage disease is caused by the absence or deficiency of glucose-6-phosphatase activity in the liver, kidney, and intestinal mucosa. It can be divided into two subtypes: type Ia, in which the glucose 6-phosphatase enzyme is defective, and type Ib, in which a translocase that transports glucose-6-phosphate across the microsomal membrane is defective. The defects in both type Ia and type Ib lead to inadequate hepatic conversion of glucose-6-phosphate to glucose and make affected individuals susceptible to fasting hypoglycemia.

Type I glycogen storage disease is an autosomal recessive disorder. The structure gene for glucose-6-phosphatase is on chromosome 17q21 and the gene for translocase is on chromosome 11q23. Common mutations responsible for the disease are known. Carrier detection and prenatal diagnosis are possible with the DNA-based diagnosis.

Clinical Manifestations.

Patients with type I glycogen storage disease may present in the neonatal period with hypoglycemia and lactic acidosis; however, they more commonly present at 3–4 mo of age with hepatomegaly or hypoglycemic seizures, or both. These children often have doll-like faces with fat cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is due to massive hepatomegaly; the kidneys are also enlarged, whereas the spleen and heart are normal.

The hallmarks of the disease are hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Hypoglycemia and lactic acidosis can develop after a short fast. Hyperuricemia is present in young children; gout rarely develops before puberty. Despite marked hepatomegaly, the liver transaminase levels are usually normal or only slightly elevated. Intermittent diarrhea may occur (the mechanism is unknown). Easy bruising and epistaxis are common and are associated with a prolonged bleeding time as a result of impaired platelet aggregation and adhesion.

The plasma may be “milky” in appearance as a result of a striking elevation of triglyceride levels. Cholesterol and phospholipids are also elevated, but less prominently. The lipid abnormality resembles type IV hyperlipidemia and is characterized by increased levels of very low density lipoprotein, low-density lipoprotein, and a unique apolipoprotein profile consisting of increased levels of apo B, C, and E, with relatively normal or reduced levels of apo A and D. The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and fat. The lipid vacuoles are particularly large and prominent. There is little associated fibrosis.

All these findings apply to both type Ia and type Ib glycogen storage disease, but type Ib has additional features of recurrent bacterial infections from neutropenia and impaired neutrophil function. Oral and intestinal mucosal ulceration and inflammatory bowel disease are common. Exceptional cases of type Ib without neutropenia and type Ia with neutropenia have been reported.

Although type I glycogen storage disease affects mainly the liver, multiple organ systems are involved. Puberty is often delayed. Virtually all females have ultrasound

findings consistent with polycystic ovaries; the other features of polycystic ovary syndrome such as acne and hirsutism are not seen. It remains to be seen whether this ovarian finding actually affects ovulation and fertility. Symptoms of gout usually start around puberty from long-term hyperuricemia. Secondary to the lipid abnormalities, there is an increased risk of pancreatitis. The dyslipidemia together with elevated erythrocyte aggregation predisposes these patients for atherosclerosis. Premature atherosclerosis, however, has not yet been clearly documented except for rare cases. Impaired platelet aggregation and of lipoproteins to oxidation may function as a protective mechanism to help reduce the risk of atherosclerosis. Frequent fractures and radiographic evidence of osteopenia are not uncommon in adult patients, and radial bone mineral content is significantly reduced in the prepubertal patients.

By the 2nd or 3rd decade of life, most patients with type I glycogen storage disease exhibit hepatic adenomas that can hemorrhage and in some cases may become malignant. Other complications include pulmonary hypertension and renal disease.

TABLE 76.1-1 -- **Features of the Disorders of Carbohydrate Metabolism**

Disorders	Basic Defects	Clinical Presentation	Comments
Liver Glycogenoses			
Type/Common Name			
Ia/Von Gierke	Glucose-6-phosphatase	Growth retardation, hepatomegaly, hypoglycemia; elevated blood lactate, cholesterol, triglyceride, and uric acid levels	Common, severe hypoglycemia
Ib	Glucose-6-phosphate translocase	Same as type Ia, with additional findings of neutropenia and impaired neutrophil function	10% of type Ia
II/Pompe Infantile	Acid maltase (acid a-glucosidase)	Cardiomegaly, hypotonia, hepatomegaly; onset: birth—6 mo	Common, cardiorespiratory failure leading to death by age 2 yr
Juvenile	Acid maltase (acid a-glucosidase)	Myopathy, variable cardiomyopathy; onset: childhood	Residual enzyme activity
Adult	Acid maltase (acid a-glucosidase)	Myopathy, respiratory insufficiency; onset: adulthood	Residual enzyme activity
IIIa/Cori or Forbes	Liver and muscle debrancher deficiency (amylo, 1,6 glucosidase)	Childhood: hepatomegaly, growth retardation, muscle weakness, hypoglycemia, hyperlipidemia, elevated transaminase levels; liver symptoms improve with age	Common, intermediate severity of hypoglycemia
IIIb	Liver debrancher deficiency; normal muscle enzyme activity	Liver symptoms same as in type IIIa; no muscle symptoms	15% of type III
IV/Andersen	Branching enzyme	Failure to thrive, hypotonia, hepatomegaly, splenomegaly, progressive cirrhosis (death usually before 5th yr), elevated transaminase levels	Rare neuromuscular variants exist
VI/ Hers	Liver phosphorylase	Hepatomegaly, mild hypoglycemia, hyperlipidemia, and ketosis	Rare, benign glycogenosis
Phosphorylase kinase deficiency	Phosphorylase kinase	Hepatomegaly, mild hypoglycemia, hyperlipidemia, and ketosis	Common, benign glycogenosis
Glycogen synthetase deficiency	Glycogen synthetase	Early morning drowsiness and fatigue, fasting hypoglycemia, and ketosis	Decreased liver glycogen store

Fanconi-Bickel syndrome	Glucose transporter-2 (GLUT-2)	Failure to thrive, rickets, hepatorenomegaly, proximal renal tubular dysfunction, impaired glucose and galactose utilization	GLUT-2 expressed in liver, kidney, pancreas, and intestine
Muscle Glycogenoses			
Type/Common Name			
V/McArdle	Myophosphorylase	Exercise intolerance, muscle cramps, increased fatigability	Common, male predominance
VII/Tarui	Phosphofructokinase	Exercise intolerance, muscle cramps, hemolytic anemia, myoglobinuria	Prevalent in Japanese and Ashkenazi Jews
Phosphoglycerate kinase deficiency	Phosphoglycerate kinase	As with type V	Rare, X-linked
Phosphoglycerate mutase deficiency	M subunit of phosphoglycerate mutase	As with type V	Rare, majority of patients are African-American
Lactate dehydrogenase deficiency	M subunit of lactate dehydrogenase	As with type V	Rare
Galactose Disorders:			
Galactosemia with transferase deficiency	Galactose-1-phosphate uridyltransferase	Vomiting, hepatomegaly, cataracts, aminoaciduria, failure to thrive	African-American patients tend to have milder symptoms
Galactokinase deficiency	Galactokinase	Cataracts	Benign
Generalized uridine diphosphate galactose-4-epimerase deficiency	Uridine diphosphate galactose 4-epimerase	Similar to transferase deficiency with additional findings of hypotonia and nerve deafness	A benign variant exists
Fructose Disorders:			
Essential fructosuria	Fructokinase	Urine reducing substance	Benign
Hereditary fructose intolerance	Fructose-1-phosphate aldolase	Acute: vomiting, sweating, lethargy Chronic: failure to thrive, hepatic failure	Prognosis good with fructose restriction
Disorders of Gluconeogenesis:			
Fructose-1,6-diphosphatase deficiency	Fructose-1,6-disphosphatase	Episodic hypoglycemia, apnea, acidosis	Good prognosis, avoid fasting
Phosphoenolpyruvate carboxykinase deficiency	Phosphoenolpyruvate carboxykinase	Hypoglycemia, hepatomegaly, hypotonia, failure to thrive	Rare
Disorders of Pyruvate Metabolism:			
Pyruvate dehydrogenase complex defect	Pyruvate dehydrogenase	Severe fatal neonatal to mild late onset, lactic acidosis, psychomotor retardation, and failure to thrive	Most commonly due to E1 a-subunit defect X-linked
Pyruvate carboxylase deficiency	Pyruvate carboxylase	Same as above	Rare, autosomal recessive
Respiratory chain defects (oxidative phosphorylation disease)	Complex I to V, many mitochondrial DNA mutations	Heterogeneous with multisystem involvement	Mitochondrial inheritance
Other Carbohydrate Disorders:			
Pentosuria	L-Xylulose reductase	Urine reducing substance	Benign

Renal disease is a late complication, and most patients with type I glycogen storage disease older than age 20 yr have proteinuria. Many also have hypertension, renal stones, nephrocalcinosis, and altered creatinine clearance. Glomerular hyperfiltration, increased renal plasma flow, and microalbuminuria are often found in the early stages of renal dysfunction and can occur before the onset of proteinuria. In younger patients, hyperfiltration and hyperperfusion may be the only signs of renal abnormalities. With the advancement of renal disease, focal segmental glomerulosclerosis and interstitial fibrosis become evident. In some patients, renal function has deteriorated and progressed to failure, requiring dialysis and transplantation. Other renal abnormalities include amyloidosis, a Fanconi-like syndrome, hypocitraturia, hypercalciuria, and a distal renal tubular acidification defect.

Diagnosis.

The diagnosis of type I glycogen storage disease can be suspected on the basis of clinical presentation and abnormal lactate and lipid values. Administration of glucagon or epinephrine results in little or no rise in blood glucose level, but the lactate level rises significantly. A definitive diagnosis requires a liver biopsy to demonstrate a deficiency of either glucose-6-phosphatase activity or translocase. Identification of the mutations for glucose-6-phosphatase or the translocase gene allows a noninvasive diagnostic method for a majority of patients with type I glycogen storage disease.

Treatment.

This is designed to maintain normal blood glucose levels and is achieved by continuous nasogastric infusion of glucose or oral administration of uncooked cornstarch. Nasogastric drip feeding can be introduced in early infancy from the time of diagnosis. It may consist of an elemental enteral formula, or it may contain only glucose or glucose polymer to provide sufficient glucose to maintain normoglycemia during the night. Frequent feedings with high carbohydrate content are given during the day.

Uncooked cornstarch acts as a slow-release form of glucose and can be introduced at a dose of 1.6?g/kg every 4?hr for infants younger than 2 yr of age. The response of young infants is variable. As the child grows older, the cornstarch regimen can be changed to every 6?hr at a dose of 1.75 to 2.5?g/kg of body weight. Because fructose and galactose cannot be converted directly to glucose, their dietary intake should be restricted, and dietary supplements of multivitamins and calcium are required. Dietary therapy improves hyperuricemia, hyperlipidemia, and renal function, slowing the development of renal failure. However, this therapy fails to completely normalize blood uric acid and lipids levels, especially after puberty. The control of hyperuricemia can be further augmented by the use of allopurinol, a xanthine oxidase inhibitor. The hyperlipidemia can be reduced with lipid-lowering drugs such as HMG-CoA reductase inhibitors and fibrate (see Chapter 75.3). Microalbuminuria is an early indicator of renal dysfunction in type I disease and can be treated with angiotensin-converting enzyme (ACE) inhibitors, such as captopril. Citrate supplement may be beneficial in preventing or ameliorating nephrocalcinosis and development of urinary calculi.

In patients with type Ib glycogen storage disease, granulocyte and granulocyte-macrophage colony-stimulating factors are successful in correcting the neutropenia, decreasing the number and severity of bacterial infections, and improving the chronic inflammatory bowel disease.

Orthotopic liver transplantation (OLT) is advocated as a potential cure of type I glycogen storage disease by some groups, but the inherent short- and long-term complications leave this as a treatment of last resort, usually for patients with liver malignancy. A large adenoma may be treated with percutaneous ethanol injection. Before any surgical procedure, the bleeding status should be evaluated, and good metabolic control should be established. Prolonged bleeding times can be normalized by the use of intensive intravenous glucose infusion for 24–48?hr before surgery. Use of 1-deamino-8-D-arginine vasopressin can reduce bleeding complications. Lactated Ringer solution should be avoided because it contains lactate and no glucose. Glucose levels should be maintained in the normal range throughout surgery with the use of 10% dextrose.

Prognosis.

Previously, patients with type I glycogen storage disease died, and the prognosis was guarded for those who survived. The long-term complications occur mostly in adults whose disease was not adequately treated during childhood. Early diagnosis and effective treatment have now greatly improved the outcome; however, renal disease and formation of hepatic adenomas remain serious complications.

Type III Glycogen Storage Disease (Debrancher Deficiency, Limit Dextrinosis)

Type III glycogen storage disease is caused by a deficiency of glycogen debranching enzyme activity. Debranching enzymes together with phosphorylase are responsible for complete degradation of glycogen; when debranching enzyme is defective, glycogen breakdown is incomplete and an abnormal glycogen with short outer branch chains and resembling limit dextrin accumulates.

Type III glycogenosis is an autosomal recessive disease that has been reported in many different ethnic groups; the frequency is relatively high in non-Ashkenazic Jews of North African extraction. The gene for debranching enzyme is located on chromosome 1p21. More than 30 different mutations are identified; two exon 3 mutations (17delAG and Q6X) are specifically associated with glycogenosis IIIb, a subtype of glycogenosis III without muscle involvement. Carrier detection and prenatal diagnosis are possible using DNA-based linkage or mutation analysis.

Deficiency of glycogen debranching enzyme causes hepatomegaly, hypoglycemia, short stature, variable skeletal myopathy, and cardiomyopathy. The disorder usually involves both liver and muscle and is termed *type IIIa glycogen storage disease*. However, in about 15% of patients, the disease appears to involve only liver and is classified as type IIIb (Fig. 76–2).

Clinical Manifestations.

During infancy and childhood, the disease may be indistinguishable from type I glycogen storage disease, because hepatomegaly, hypoglycemia, hyperlipidemia, and growth retardation are common. Splenomegaly may be present, but the kidney is not enlarged. Remarkably, hepatomegaly and hepatic symptoms in most patients with type III glycogen storage disease improve with age and usually resolve after puberty. Progressive liver cirrhosis and failure may occur and is common in Japanese patients. Hepatic adenomas have been reported; their prevalence may be as high as 25% in French patients. Malignant transformation of adenomas has not been observed, although two patients developed a hepatocellular carcinoma associated with end-stage liver cirrhosis. In patients with muscular involvement (type IIIa), muscle weakness is usually minimal during childhood but can become severe after the 3rd or 4th decade of life, as evidenced by slowly progressive weakness and wasting. Electromyography changes are consistent with a widespread myopathy, and nerve conduction studies may be abnormal. Ventricular hypertrophy is a

frequent finding, but overt cardiac dysfunction is rare. Hepatic symptoms in some patients may be so mild that the diagnosis is not made until adulthood, when the patients show symptoms and signs of neuromuscular disease. The initial diagnosis has been confused with Charcot-Marie-Tooth disease. Polycystic ovary appears to be common; the fertility, however, is not reduced.

Hypoglycemia and hyperlipidemia are common. In contrast to type I glycogen storage disease, elevation of liver transaminase levels and fasting ketosis are prominent, but blood lactate

---

Figure 76.1-2 Growth and development in a patient with type IIIb glycogen storage disease. The patient has debrancher deficiency in liver but normal activity in muscle. As a child he had hepatomegaly, hypoglycemia, and growth retardation. After puberty, he no longer had hepatomegaly or hypoglycemia, and his final adult height is normal. He has no muscle weakness or atrophy; this is in contrast to type IIIa patients, in whom a progressive myopathy is seen in adulthood.

and uric acid concentrations are usually normal. The administration of glucagon 2?hr after a carbohydrate meal provokes a normal increase in blood glucose, but after an overnight fast, glucagon may provoke no change in blood glucose level. Serum creatine kinase levels may be useful to identify patients with muscle involvement; normal levels do not rule out muscle enzyme deficiency.

Diagnosis.

The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III glycogenosis from type I. The fibrosis, which ranges from minimal periportal fibrosis to micronodular cirrhosis, in most cases appears to be nonprogressive.

Patients with myopathy and liver symptoms have a generalized enzyme defect (type IIIa). The deficient enzyme activity can be demonstrated not only in liver and muscle but also in other tissues such as heart, erythrocytes, and cultured fibroblasts. Patients with hepatic symptoms without clinical or laboratory evidence of myopathy have debranching enzyme deficiency only in the liver, with enzyme activity retained in the muscle (type IIIb). Definite diagnosis requires enzyme assay in liver or muscle, or both. Mutation analysis can provide a noninvasive method for diagnosis and subtype assignment in the majority of patients.

Treatment.

Dietary management is less demanding than in type I glycogen storage disease. If hypoglycemia is present, frequent meals high in carbohydrates with cornstarch supplements or nocturnal gastric drip feedings are usually effective. A high-protein diet during the daytime plus overnight protein enteral infusion may also be effective in preventing hypoglycemia, because protein can be used as substrate for gluconeogenesis, a pathway that is intact in type III glycogen storage disease. There is no satisfactory treatment for the progressive myopathy. Patients do not need to restrict dietary intake of fructose and galactose. Liver transplantation has been performed in patients with end-stage cirrhosis and/or hepatic carcinoma.

Type IV Glycogen Storage Disease (Branching Enzyme Deficiency, Amylopectinosis, or Andersen Disease)

Deficiency of branching enzyme activity results in accumulation of an abnormal glycogen with poor solubility. The disease is referred to as type IV glycogen storage disease or amylopectinosis because the abnormal glycogen has fewer branch points, more a1-4 linked glucose units, and longer outer chains, resulting in a structure resembling amylopectin.

Type IV glycogen storage disease is an autosomal recessive disorder. The glycogen branching enzyme gene is located on chromosome 3p21. Mutations responsible for type IV glycogen storage disease have been identified, and their characterization in individual patients may be useful in predicting the clinical outcome.

Clinical Manifestations.

This disorder is clinically variable. The most common and classic form is characterized by progressive cirrhosis of the liver and is manifested in the first 18 mo of life as hepatosplenomegaly and failure to thrive. The cirrhosis progresses to portal hypertension, ascites, esophageal varices, and liver failure that leads to death by 5 yr of age. Rare patients survive without progression of liver disease.

A neuromuscular form of the disease has been reported. These patients may (1) present at birth with severe hypotonia, muscle atrophy, and neuronal involvement with death in the neonatal period; (2) present in late childhood with myopathy or cardiomyopathy; or (3) present as adults with diffuse central and peripheral nervous system dysfunction accompanied by accumulation of polyglucosan body disease in the nervous system (so-called *adult polyglucosan body disease*). For adult polyglucosan disease, leukocyte or nerve biopsy is needed to establish the diagnosis, because the branching enzyme deficiency is limited to those tissues.

Diagnosis.

Tissue disposition of amylopectin-like materials can be demonstrated in liver, heart, muscle, skin, intestine, brain, spinal cord, and peripheral nerve. The hepatic histologic findings are characterized by micronodular cirrhosis and faintly stained basophilic inclusions in the hepatocytes. The inclusions consist of coarsely clumped, stored material that is periodic acid–Schiff positive and partially resistant to diastase digestion. Electron microscopy shows, in addition to the conventional a and ß glycogen particles, accumulation of the fibrillar aggregations that are typical of amylopectin. The distinct staining properties of the cytoplasmic inclusions, as well as electron microscopic findings, could be diagnostic. However, polysaccharidoses with histologic features reminiscent of type IV disease, but without enzymatic correlation, have been observed. The definitive diagnosis rests on the demonstration of the deficient branching enzyme activity in liver, muscle, cultured skin fibroblasts, or leukocytes. Prenatal diagnosis is possible by measuring the enzyme activity in

cultured amniocytes or chorionic villi.

Treatment.

There is no specific treatment for type IV glycogen storage disease. For progressive hepatic failure, liver transplantation has been performed, but because it is a multisystem disorder involving many organ systems, the long-term success of liver transplantation is unknown.

Type VI Glycogen Storage Disease (Liver Phosphorylase Deficiency, HERS Disease)

There are few patients with documented liver phosphorylase deficiency. Such patients have a benign course and present with hepatomegaly and growth retardation in early childhood. Hypoglycemia, hyperlipidemia, and hyperketosis are usually

---

mild if present. Lactic acid and uric acid levels are normal. The heart and skeletal muscles are not involved. The hepatomegaly and growth retardation improve with age and usually disappear around puberty. Treatment is symptomatic. A high-carbohydrate diet and frequent feeding are effective in preventing hypoglycemia; most patients require no specific treatment. The liver phosphorylase gene is located on chromosome 14q21-22; mutations responsible for the disease are known.

Type IX Glycogen Storage Disease (Phosphorylase Kinase Deficiency)

This disorder represents a heterogeneous group of glycogenoses. Phosphorylase, the rate-limiting enzyme of glycogenolysis, is activated by a cascade of enzymatic reactions involving adenylate cyclase, cyclic adenosine monophosphate–dependent protein kinase (protein kinase A), and phosphorylase kinase. The latter enzyme has four subunits, each encoded by different genes on different chromosomes and differentially expressed in various tissues. This cascade of reactions is stimulated primarily by glucagon. This glycogenosis could be the result of any enzyme deficiency along this pathway; the most common is the deficiency of phosphorylase kinase.

The numeric classification of phosphorylase kinase deficiency is confusing, ranging from type VIa to VIII to IX. It is advisable to refrain from such a designation and to classify the various disorders according to organ involvement and mode of inheritance.

X-Linked Liver Phosphorylase Kinase Deficiency.

This is a common form of liver glycogenoses. Enzyme activity may also be deficient in erythrocytes and leukocytes; it is normal in muscle. Typically a 1–5 yr old presents with growth retardation and an incidental finding of hepatomegaly. Cholesterol, triglycerides, and liver enzymes are mildly elevated. Ketosis may occur after fasting. Lactate and uric acid levels are normal. Hypoglycemia is mild, if present. The response in blood glucose to glucagon is normal. Hepatomegaly and abnormal blood chemistries gradually become normal with age. Most adults achieve a normal final height and are usually asymptomatic despite a persistent phosphorylase kinase deficiency. Liver histologic appearance shows glycogen-distended hepatocytes. The accumulated glycogen (a particles, rosette form) has a frayed or burst appearance and is less compact than the glycogen seen in type I or type III glycogen storage disease. Fibrous septal formation and low-grade inflammatory changes may be present.

The structural gene for the liver isoform of the phosphorylase kinase a subunit is located on chromosome Xp22; mutations of this gene are known.

Autosomal Liver and Muscle Phosphorylase Kinase Deficiency

Several patients have been reported with phosphorylase kinase deficiency in liver and blood cells and an autosomal model of inheritance. As with the X-linked form, hepatomegaly and growth retardation apparent in early childhood are the predominant symptoms. Some also exhibited muscle hypotonia. When measured in a few cases, reduced activity of the enzyme has been demonstrated in muscle. Mutations causing autosomally transmitted liver and muscle phosphorylase kinase deficiency are found in the autosomal gene of the subunit ß.

Autosomal Liver Phosphorylase Kinase Deficiency

This form of phosphorylase kinase deficiency is due to mutations in the testis/liver isoform of the ? subunit of the gene (*PHKG2*, ? subunit). In contrast to the benign course of X-linked phosphorylase kinase deficiency, patients with mutations in the *PHKG2* gene have more severe phenotypes and often develop liver cirrhosis

Muscle-Specific Phosphorylase Kinase Deficiency

A few cases of phosphorylase kinase deficiency restricted to muscle are known. Patients, both male and female, present either with muscle cramps and myoglobinuria with exercise or with progressive muscle weakness and atrophy. Phosphorylase kinase activity is decreased in muscle but normal in liver and blood cells. There is no hepatomegaly or cardiomegaly. Mutation in the structure gene of muscle isoform of the a subunit is located on chromosome Xq12; mutation of this gene has been found in male patients with this disorder.

Phosphorylase Kinase Deficiency Limited to Heart

These patients present with cardiomyopathy in infancy and rapidly progress to heart failure and death. Phosphorylase kinase deficiency is demonstrated in heart with normal enzyme activity in skeletal muscle and liver.

Diagnosis.

Definitive diagnosis of phosphorylase kinase deficiency requires demonstration of the enzymatic defect in affected tissues. Phosphorylase kinase can be measured in

leukocytes and erythrocytes, but because the enzyme has many isozymes, the diagnosis can be missed without studies of liver, muscle, or heart.

Treatment.

The treatment for liver phosphorylase kinase deficiency includes high-carbohydrate diet and frequent feedings to prevent hypoglycemia; most patients require no specific treatment. Prognosis is good. There is currently no treatment for the fatal form of isolated cardiac phosphorylase kinase deficiency other than heart transplantation.

Glycogen Synthetase Deficiency

Deficiency of hepatic glycogen synthetase leads to a marked decrease of glycogen stored in the liver. The patients present in infancy with early-morning (before eating breakfast) drowsiness, pallor, emesis, and fatigue and sometimes convulsions associated with hypoglycemia and hyperketonemia. Blood lactate and alanine levels are low, and there is no hyperlipidemia or hepatomegaly. Prolonged hyperglycemia and elevation of lactate with normal insulin levels after administration of glucose suggest a possible diagnosis of deficiency of glycogen synthetase. Definitive *diagnosis* requires a liver biopsy to measure the enzyme activity. *Treatment* consists of frequent meals, rich in protein, and nighttime supplementation with uncooked cornstarch. The disease is due to the mutations in the liver glycogen synthetase gene, located on chromosome 12p12.2.

Hepatic Glycogenosis with Renal Fanconi Syndrome (Fanconi-Bickel Syndrome)

This rare autosomal recessive disorder is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports glucose in and out of hepatocytes, pancreatic beta cells, and the basolateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney.

The affected child presents *clinical manifestations* in the 1st yr of life with failure to thrive, rickets, and a protuberant abdomen from hepatomegaly and renomegaly. Laboratory findings include glucosuria, phosphaturia, generalized aminoaciduria, bicarbonate wasting, hypophosphatemia, increased serum alkaline phosphatase levels, and a radiologic finding of rickets. Mild fasting hypoglycemia and hyperlipidemia may be present. Liver transaminase, plasma lactate, and uric acid levels are usually normal. Oral galactose or glucose tolerance tests show

intolerance, which could be explained by the functional loss of GLUT-2 preventing liver uptake of these sugars.

Tissue biopsy results show marked accumulation of glycogen in hepatocytes and proximal renal tubular cells, presumably owing to the altered glucose transport out of these organs.

There is no specific *treatment*. Growth retardation persists through adulthood. Symptomatic replacement of water, electrolytes, and vitamin D; restriction of galactose intake; and a diet similar to that used for diabetes mellitus presented in frequent and small meals with an adequate caloric intake may improve growth.

MUSCLE GLYCOGENOSES

The role of glycogen in muscle is to provide substrates for the generation of ATP for muscle contraction. The muscle glycogen storage diseases are divided into two groups. The first is characterized by progressive skeletal muscle weakness and atrophy or cardiomyopathy, or both, and is represented by a lysosomal glycogen degrading enzyme deficiency of acid a-glucosidase (type II glycogen storage disease). The second is a muscle energy disorder characterized by muscle pain, exercise intolerance, myoglobinuria, and susceptibility to fatigue. This group includes myophosphorylase deficiency (McArdle disease, type V) and deficiencies of phosphofructokinase (type VII), phosphoglycerate kinase, phosphoglycerate mutase, or lactate dehydrogenase. Some of these latter enzyme deficiencies may also be associated with a compensated hemolysis, suggesting a more generalized defect in glucose metabolism.

Type II (Lysosomal Acid a1,4-Glucosidase Deficiency, Pompe Disease)

Type II glycogen storage disease is caused by a deficient activity of lysosomal acid a1,4 glucosidase (acid maltase), an enzyme responsible for the degradation of glycogen in lysosome. The disease is characterized by accumulation of glycogen in lysosomes as opposed to its accumulation in cytoplasm in the other glycogenoses.

Pompe disease is an autosomal recessive disorder with an incidence of 1/40,000 live births with no ethnic predilection. The gene for acid a-glucosidase is on chromosome 17q25.2. A splice site mutation (IVS1-13T?G), commonly seen in adult-onset patients, may be helpful in delineating the phenotypes.

Clinical Manifestations.

The disorder encompasses a range of phenotypes, each including myopathy but differing in age at onset, organ involvement, and clinical severity. The most severe is the *infantile-onset disease*, with prominent cardiomegaly, hypotonia, and death before 2 yr of age. Infants appear normal at birth but soon experience generalized muscle weakness with “floppy infant appearance,” feeding difficulties, macroglossia, hepatomegaly, and heart failure from a progressively hypertrophic cardiomyopathy. Electrocardiographic findings include a high-voltage QRS complex and a shortened PR interval. Death usually results from cardiorespiratory failure or aspiration pneumonia.

The *juvenile form* presents as delayed motor milestones (if age at onset is early enough) or difficult walking in childhood and is followed by swallowing difficulties, proximal muscle weakness, and respiratory muscle involvement. Death from respiratory failure may occur before the end of the 2nd decade. Cardiomegaly is

variable, but overt cardiac failure is not seen.

An *adult form* of type II disease presents as a slowly progressive myopathy without cardiac involvement and has its onset between the 2nd and 7th decades. The clinical picture is dominated by slowly progressive proximal muscle weakness with truncal involvement and greater involvement of the lower limbs than the upper limbs. The pelvic girdle, paraspinal muscle, and diaphragm are the muscle groups most seriously affected. The initial symptoms in some patients may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea, which eventually lead to sleep-disordered breathing and respiratory failure.

Laboratory Findings.

These include elevated levels of serum creatine kinase, aspartate aminotransferase, and lactate dehydrogenase. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen; acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. Electron microscopy reveals the glycogen accumulation within the membranous sac and in the cytoplasm. Electromyography reveals myopathic features with excessive electrical irritability of muscle fibers and pseudomyotonic discharges. Serum creatine kinase is not always elevated in adult patients; depending on the muscle sampled or tested, the muscle histologic appearance on electromyography may not be abnormal. It is prudent to examine the affected muscle.

Diagnosis.

This can be established by demonstration of the absence of or reduced levels of acid a-glucosidase activity in muscle, cultured skin fibroblast, or blood spots. Deficiency is usually more severe in the infantile form than in the juvenile and adult forms. Prenatal diagnosis using amniocytes or chorionic villi is available in the fatal infantile form. A lysosomal glycogen storage disease clinically similar to late-onset type II glycogenosis, but with normal acid a-glucosidase activity, is caused by defects in lysosomal associated membrane protein-2.

Treatment.

Definitive therapy is not available; a high-protein diet may be useful for the juvenile and adult forms. Nocturnal ventilatory support in late-onset patients improves the quality of life and is beneficial during a period of respiratory decompensation. Preliminary clinical trials of enzyme replacement therapy have shown that recombinant acid a-glucosidase is capable of improving cardiac and skeletal muscle functions in these patients.

Type V (Muscle Phosphorylase Deficiency, McArdle Disease)

Lack of this enzyme limits muscle ATP generation by glycogenolysis, results in glycogen accumulation, and is the prototype of muscle energy disorder.

Clinical Manifestations.

Symptoms usually first develop in late childhood or as an adult and are characterized by exercise intolerance with muscle cramps. Two types of activity tend to cause symptoms: (1) brief exercise of great intensity, such as sprinting or carrying heavy loads, and (2) less intense but sustained activity, such as climbing stairs or walking uphill. Moderate exercise, such as walking on level ground, can be performed by most patients for long periods. Many patients experience a characteristic “second wind” phenomenon. If they slow down or pause briefly at the first appearance of muscle pain, they can resume exercise with more ease.

About half report burgundy-colored urine after exercise, which is the consequence of myoglobinuria secondary to rhabdomyolysis. Intense myoglobinuria after vigorous exercise may cause acute renal failure. In rare cases, electromyographic findings may suggest an inflammatory myopathy and the diagnosis can be confused with polymyositis.

The level of serum creatine kinase is usually elevated at rest and increases more after exercise. Exercise also increases the levels of blood ammonia, inosine, hypoxanthine, and uric acid. The latter abnormalities are attributed to accelerated recycling of muscle purine nucleotides owing to insufficient ATP production.

Clinical heterogeneity is uncommon in type V glycogen storage disease, but late-onset disease with no symptoms as late as the 8th decade and an early-onset, fatal form with hypotonia, generalized muscle weakness, and progressive respiratory insufficiency have been described.

Diagnosis.

An ischemic exercise test offers rapid diagnostic screening for metabolic myopathy. Lack of an increase in blood lactate levels and exaggerated blood ammonia elevations indicate muscle glycogenosis and suggest a defect in the conversion of muscle glycogen or glucose to lactate. The abnormal ischemic exercise response is not limited to type V glycogen storage disease. Other muscle defects in glycogenolysis or glycolysis produce similar results (deficiencies of muscle phosphofructokinase, phosphoglycerate kinase, phosphoglycerate mutase, or lactate dehydrogenase).

Phosphorus magnetic resonance imaging (^{31}P MRI) allows for the noninvasive evaluation of muscle metabolism. Patients with type V glycogen storage disease have no decrease in intracellular pH and have excessive reduction in phosphocreatine in response to exercise. The diagnosis should be confirmed by enzymatic evaluation of muscle.

Type V glycogen storage disease is an autosomal recessive disorder. The gene for muscle phosphorylase is located on chromosome 11q13-qter. A nonsense mutation

changing arginine to a stop at codon 49 (R49X) and a deletion of a single codon (F708) are prevalent in white and Japanese patients, respectively. This allows DNA-based diagnosis and carrier detection for the two populations.

Treatment.

Avoidance of strenuous exercise prevents the symptoms; however, regular and moderate exercise is recommended to improve exercise capacity. Exercise tolerance can also be augmented by oral administration of glucose or fructose or by injection of glucagon. A high-protein diet may increase muscle endurance. Creatine supplement improves muscle function in some patients. Longevity is not generally affected.

Type VII Glycogen Storage Disease (Muscle Phosphofructokinase Deficiency, Tarui Disease)

Type VII glycogen storage disease is caused by a deficiency of muscle phosphofructokinase, which catalyzes the ATP-dependent conversion of fructose-6-phosphate to fructose-1,6-diphosphate and is a key regulatory enzyme of glycolysis. Phosphofructokinase is composed of three isoenzyme subunits (M [muscle], L [liver], and P [platelet]) that are encoded by different genes and differentially expressed in tissues. Skeletal muscle contains only the M subunit, and red blood cells contain a hybrid of L and M forms. Type VII disease is due to a defective M isoenzyme, which causes a complete enzyme defect in muscle and a partial defect in red blood cells.

Type VII glycogen storage disease is an autosomal recessive disorder and is prevalent among Japanese people and Ashkenazi Jews. The gene for muscle phosphofructokinase is located on chromosome 1cen-1q32. A splicing defect and a nucleotide deletion in the muscle phosphofructokinase gene account for 95% of mutant alleles in Ashkenazi Jews. The molecular diagnosis is possible in this population.

Clinical Manifestations.

Five features of type VII are distinctive: (1) Exercise intolerance, usually evident in childhood, is more severe than in type V disease and may be associated with nausea and vomiting. Vigorous exercise causes severe muscle cramps and myoglobinuria. (2) A compensated hemolysis occurs as evidenced by an increased level of serum bilirubin and an elevated reticulocyte count. (3) Hyperuricemia is common and exaggerated by muscle exercise to a more severe degree than that observed in type V or III glycogen storage disease. (4) An abnormal glycogen resembling amylopectin is present in muscle fibers; it is periodic acid–Schiff positive but resistant to diastase digestion. (5) Exercise intolerance is particularly acute after meals that are rich in carbohydrates because glucose cannot be utilized in muscle and because glucose inhibits lipolysis and thus deprives muscle of fatty acid and ketone substrates. In contrast, patients with type V disease can metabolize bloodborne glucose derived from either liver glycogenolysis or exogenous glucose. Indeed, glucose infusion improves exercise tolerance in type V patients.

Two rare type VII variants occur. One variant presents in infancy with hypotonia and limb weakness and proceeds to a rapidly progressive myopathy that leads to death by 4 yr of age. The other variant presents in adults and is characterized by a slowly progressive, fixed muscle weakness rather than cramps and myoglobinuria.

Diagnosis.

To establish a diagnosis, a biochemical or histochemical demonstration of the enzymatic defect in the muscle is required. The absence of the M isoenzyme of phosphofructokinase can also be demonstrated in blood cells and fibroblasts.

Treatment.

There is no specific treatment. Avoidance of strenuous exercise is advisable to prevent acute attacks of muscle cramps and myoglobinuria.

Other Muscle Glycogenoses with Muscle Energy Impairment

Six additional enzyme defects—phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose-1,6-biphosphate aldolase A, muscle pyruvate kinase, and ß-enolase in the pathway of the terminal glycolysis—cause symptoms and signs of muscle energy impairment similar to those of types V and VII glycogen storage disease. The failure of blood lactate to increase in response to exercise is a useful diagnostic test and can be used to differentiate muscle glycogenoses from disorders of lipid metabolism, such as carnitine palmitoyl transferase II deficiency and very long chain acyl-CoA dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels may be normal in the disorders affecting terminal glycolysis; assaying the muscle enzyme activity makes a definite diagnosis. There is no specific treatment. Avoidance of strenuous exercise prevents acute attacks of muscle cramps and myoglobinuria.

76.2 Defects in Galactose Metabolism

Yuan-Tsong Chen

Milk and dairy products contain lactose, the major dietary source of galactose. The metabolism of galactose produces fuel for cellular metabolism through its conversion to glucose-1-phosphate (see Fig. 76–1 (Figure Not Available)). Galactose also plays an important role in the formation of galactosides, which include glycoproteins, glycolipids, and glycosaminoglycans. Galactosemia denotes the elevated level of galactose in the blood and is found in three distinct disorders of galactose metabolism defective in one of the following enzymes: galactose-1-phosphate uridyl transferase, galactokinase, and uridine diphosphate galactose-4-epimerase. The term *galactosemia*, although adequate for the deficiencies for any of these three disorders, generally designates the transferase deficiency.

GALACTOSE-1-PHOSPHATE URIDYL TRANSFERASE DEFICIENCY GALACTOSEMIA

“Classic” galactosemia is a serious disease with early onset of symptoms; the incidence is 1/60,000. The newborn infant normally receives up to 20% of caloric intake as lactose, which consists of equal parts of glucose and galactose. Without the transferase enzyme, the infant is unable to metabolize galactose-1-phosphate, the accumulation of which results in injury to kidney, liver, and brain. This injury may begin prenatally in the affected fetus by transplacental galactose derived from the diet of the heterozygous mother or by endogenous production of galactose in the fetus.

Clinical Manifestations.

The diagnosis of uridyl transferase deficiency should be considered in newborn or young infants with

any of the following features: jaundice, hepatomegaly, vomiting, hypoglycemia, convulsions, lethargy, irritability, feeding difficulties, poor weight gain, aminoaciduria, cataracts, vitreous hemorrhage, hepatic cirrhosis, ascites, splenomegaly, or mental retardation. Patients with galactosemia are at increased risk for *Escherichia coli* neonatal sepsis; the onset of sepsis often precedes the diagnosis of galactosemia. When the diagnosis is not made at birth, damage to the liver (cirrhosis) and brain (mental retardation) becomes increasingly severe and irreversible. Galactosemia should be considered for the newborn or young infant who is not thriving or who has any of the preceding findings.

Diagnosis.

Because galactose is injurious to persons with galactosemia, diagnostic challenge tests dependent on administering galactose orally or intravenously should not be used. Galactose administration would result in high concentrations of intracellular galactose-1-phosphate, which can function as a competitive inhibitor of phosphoglucomutase. This inhibition transiently impairs the conversion of glycogen to glucose and produces hypoglycemia. Light and electron microscopy of hepatic tissue reveals fatty infiltration, the formation of pseudoacini, and eventual macronodular cirrhosis. These changes are consistent with a metabolic disease but do not indicate the precise enzymatic defect.

The preliminary diagnosis of galactosemia is made by demonstrating a reducing substance in several urine specimens collected while the patient is receiving human milk, cow's milk, or another formula containing lactose. The reducing substance found in urine by Clinitest can be identified by chromatography or by an enzymatic test specific for galactose. Clinistix or Tes-Tape urine test results are negative because the test materials rely on the action of glucose oxidase, which is specific for glucose and is nonreactive with galactose. Deficient activity of galactose-1-phosphate uridyl transferase is demonstrable in hemolysates of erythrocytes, which also exhibit increased concentrations of galactose-1-phosphate.

Genetics.

Transferase deficiency galactosemia is an autosomal recessive trait. There are several enzymatic variants of galactosemia. The Duarte variant, a single amino acid substitution (N314D) has diminished red cell enzyme activity but usually no clinical significance. Some African-American patients have milder symptoms despite the absence of measurable transferase activity in erythrocytes; these patients retain 10% enzyme activity in liver and intestinal mucosa, whereas most white patients have no detectable activity in any of these tissues. In African-Americans, 62% of alleles are represented by the S135L mutation, a mutation that is responsible for the milder disease. In the white population, 70% of alleles are represented by the Q188R and K285N missense mutations and are associated with severe disease. Carrier testing and prenatal diagnosis can be performed by direct enzyme analysis of amniocytes or chorionic villi; testing can also be DNA based.

Treatment and Prognosis.

Because of newborn screening for galactosemia, patients are being identified and treated early. Elimination of galactose from diet reverses growth failure and renal and hepatic dysfunction. Cataracts regress, and most patients have no impairment of eyesight. Early diagnosis and treatment have improved the prognosis of galactosemia; however, on long-term follow-up, patients still manifest ovarian failure with primary or secondary amenorrhea, developmental delay, and learning disabilities that increase in severity with age. Most manifest speech disorders, whereas a smaller number demonstrate poor growth and impaired motor function

and balance (with or without overt ataxia). The relative control of galactose-1-phosphate levels does not always correlate with long-term outcome, leading to the belief that other factors, such as elevated galactitol, decreased uridine diphosphate galactose (UDP-galactose, a donor for galactolipids and proteins), and endogenous galactose production may be responsible.

GALACTOKINASE DEFICIENCY

The deficient enzyme is galactokinase, which normally catalyzes the phosphorylation of galactose. The principal metabolites accumulated are galactose and galactitol. Mutations leading to autosomally inherited galactokinase deficiency are known. The gene coding for galactokinase is located on chromosome 17q24. In contrast to the multiple organs that are affected in transferase deficiency galactosemia, cataracts are usually the sole manifestation of galactokinase deficiency with pseudotumor cerebri as a rare complication. Heterozygotic carriers may have late adult onset cataracts. The affected infant is otherwise asymptomatic. These patients have an increased concentration of blood galactose levels with normal transferase activity and an absence of galactokinase activity in erythrocytes. Treatment is dietary restriction of galactose.

URIDINE DIPHOSPHATE GALACTOSE 4-EPIMERASE DEFICIENCY

The abnormally accumulated metabolites are similar to those in transferase deficiency; however, there is also an increase in cellular UDP-galactose. There are two distinct forms of epimerase deficiency. A benign form has been discovered incidentally through a neonatal screening program. Affected persons are healthy and without problems; the enzyme deficiency is limited to leukocytes and erythrocytes. No treatment is required. The second form of epimerase deficiency is severe, and clinical manifestations resemble transferase deficiency with the additional symptoms of hypotonia and nerve deafness. The enzyme deficiency is generalized, and clinical symptoms respond to restriction of dietary galactose. Although this form of galactosemia is rare, it must be considered in a symptomatic patient who has normal transferase activity.

Patients with epimerase deficiency cannot make galactose. Because it is an essential component of many nervous system structural proteins, patients are placed on a galactose-restricted diet rather than a galactose-free diet.

The gene for UDP-galactose 4-epimerase is located on chromosome 1 at 1p36. Carrier detection is possible by measurement of epimerase activity in the erythrocytes. Prenatal diagnosis for the severe form of epimerase deficiency, using an enzyme assay of cultured amniotic fluid cells is possible.

76.3 Defects in Fructose Metabolism

Yuan-Tsong Chen

DEFICIENCY OF FRUCTOKINASE (BENIGN FRUCTOSURIA)

Deficiency of fructokinase is not associated with any clinical manifestations. It is an accidental finding usually made because the asymptomatic patient's urine contains a reducing substance. No treatment is necessary. Inheritance is autosomal recessive with an incidence of 1/120,000. The gene encoding fructokinase is located on chromosome 2p23.3.

Fructokinase catalyzes the first step of metabolism of dietary fructose: conversion of fructose to fructose 1-phosphate (see Fig. 76–1 (Figure Not Available)). Without this enzyme, ingested fructose is not metabolized. Its level is increased in the blood, and it is excreted in urine because there is practically no renal threshold for fructose. Both positive and negative Clinitest results reveal the urinary-reducing substance to be something other than glucose. It can be identified as fructose by chromatography.

DEFICIENCY OF FRUCTOSE-1,6-BISPHOSPHATE ALDOLASE (ALDOLASE B) (HEREDITARY FRUCTOSE INTOLERANCE)

Deficiency of fructose-1,6-bisphosphate aldolase is a severe condition of infants that appears with the ingestion of fructose-containing food and is caused by deficiency of fructose aldolase B activity in the liver, kidney, and intestine. The enzyme catalyzes the hydrolysis of fructose-1,6-bisphosphate into triose phosphate and glyceraldehyde phosphate. The same enzyme also hydrolyzes fructose 1-phosphate. Deficiency of this enzyme activity causes a rapid accumulation of fructose-1-phosphate and initiates severe toxic symptoms when exposed to fructose.

Epidemiology and Genetics.

The true incidence of hereditary fructose intolerance is unknown but may be as high as 1/23,000. The gene for aldolase B is on chromosome 9q22.3. Several mutations causing heredity fructose intolerance are known. A single missense mutation, a G?C transversion in exon 5 resulting in the normal alanine at position 149 being replaced by a proline, is the most common mutation identified in northern Europeans. This mutation, plus two other point mutations, account for 80–85% of hereditary fructose intolerance in Europe and the United States. Diagnosis of hereditary fructose intolerance can be made by direct DNA analysis. Prenatal diagnosis should be possible by amniocentesis and chorionic villi, using DNA mutational or linkage analysis.

Clinical Manifestations.

Patients with fructose intolerance are perfectly healthy and asymptomatic until fructose or sucrose (table sugar) is ingested (usually from fruit, fruit juice, or sweetened cereal). Symptoms may occur early in life soon after birth if foods or formulas containing these sugars are introduced into the diet. Early clinical manifestations resemble galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. Laboratory findings include prolonged clotting time, hypoalbuminuria, elevation of bilirubin and transaminase levels, and proximal tubular dysfunction. Acute fructose ingestion produces symptomatic hypoglycemia; chronic ingestion results in failure to thrive and hepatic disease. If the intake of the fructose persists, hypoglycemic episodes recur, and liver and kidney failure progress, eventually leading to death.

Diagnosis.

Suspicion of the enzyme deficiency is fostered by the presence of a reducing substance in the urine during an episode. The diagnosis could be supported by an intravenous fructose tolerance test, which will cause a rapid fall, first of serum phosphate and then of blood glucose, and a subsequent increase in uric acid and magnesium. An oral tolerance test should not be performed, because patients may become acutely ill. Definitive diagnosis is made by assay of fructaldolase B activity in the liver.

Treatment.

This consists of the complete elimination of all sources of sucrose, fructose, and sorbitol from the diet. This may be difficult because these sugars are widely used additives, found even in most medicinal preparations. With treatment, liver and kidney dysfunction improves, and catch-up in growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder even after fructose ingestion; the long-term prognosis is good. Because of voluntary dietary avoidance of sucrose, affected patients have few dental caries.

76.4 Defects in Intermediary Carbohydrate Metabolism Associated with Lactic Acidosis

Yuan-Tsong Chen

Lactic acidosis occurs with defects of carbohydrate metabolism that interfere with the conversion of pyruvate to glucose via the pathway of gluconeogenesis or to carbon dioxide and water via the mitochondrial enzymes of the citric acid cycle. Figure 76–3 depicts the relevant metabolic pathways. Type I glycogen storage disease, fructose-1,6-diphosphatase deficiency, and phosphoenolpyruvate carboxylase deficiency are disorders of gluconeogenesis associated with lactic acidosis. Pyruvate dehydrogenase complex deficiency, respiratory chain defects, and pyruvate carboxylase deficiency are disorders in the pathway of pyruvate metabolism causing lactic acidosis. Lactic acidosis can also occur in defects of fatty acid oxidation, organic acidurias (see Chapters 74.6 , 74.10 , and 75.1), or biotin utilization

Figure 76.4-3 Enzymatic reactions of carbohydrate metabolism, deficiencies of which may give rise to lactic acidosis, pyruvate elevations, or hypoglycemia. The pyruvate dehydrogenase complex comprises, in addition to E_1 , E_2 , and E_3 , an extra lipoate-containing protein (not shown), called protein X, and pyruvate dehydrogenase phosphatase.

diseases. These disorders are easily distinguishable by the presence of abnormal acylcarnitine profiles in the blood and unusual organic acids in the urine. Therefore, blood lactate and acylcarnitine profiles and the presence of these unusual urine organic acids should be determined in infants and children with unexplained acidosis, especially if there is an increase of anion gap (see Chapter 48).

Lactic acidosis unrelated to an enzymatic defect occurs in hypoxemia. In this case, as well as in defects in the respiratory chain, the serum pyruvate concentration may remain normal (<1.0?mg/dL with an increased lactate:pyruvate ratio), whereas pyruvate is usually increased when lactic acidosis results from an enzymatic defect in gluconeogenesis or pyruvate dehydrogenase complex (both lactate and pyruvate are increased and the ratio is normal). Lactate and pyruvate should be measured in the same blood specimen and on multiple blood specimens obtained when the patient is symptomatic because lactic acidosis may be intermittent. An algorithm for the differential diagnosis of lactic acidosis is shown in Figure 76–4 .

Figure 76.4-4 Algorithm of the differential diagnosis of lactic acidosis.

DISORDERS OF GLUCONEOGENESIS

Deficiency of Glucose-6-Phosphatase (Type I Glycogen Storage Disease)

Type I glycogen storage disease is the only glycogenosis associated with significant lactic acidosis. The chronic metabolic acidosis predisposes these patients to osteopenia, and in an acute setting after prolonged fasting the acidosis associated with hypoglycemia is a life-threatening condition. This disease is discussed further in Chapter 76.1 .

Fructose-1,6-Diphosphatase Deficiency

Fructose-1,6-diphosphatase deficiency is not a defect in the fructose pathway; rather, it is a defect involved in gluconeogenesis. The *clinical manifestations* are characterized by life-threatening episodes of acidosis, hypoglycemia, hyperventilation, convulsions, and coma. Half of the patients have an onset in the 1st week of life. In infants and small children, episodes are triggered by febrile infections and gastroenteritis if oral food intake decreases. *Laboratory findings* include low blood glucose and high lactate and uric acid levels and metabolic acidosis. In contrast to hereditary fructose intolerance, there is usually no aversion to sweets; renal tubular and liver functions are normal.

The *diagnosis* is established by demonstrating an enzyme deficiency in either a liver or intestinal biopsy. The enzyme defect may also be demonstrated in leukocytes in some cases. The gene coding for fructose-1,6-diphosphatase is located on chromosome 9q22. Because mutations are being characterized, carrier detection and prenatal diagnosis should be possible using a DNA-based test. *Treatment* of acute attacks consists of correction of hypoglycemia and acidosis by intravenous glucose infusion; the response is usually rapid. Avoidance of fasting and restriction of fructose and sucrose from the diet prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Patients who survive childhood develop normally.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) is a key enzyme in gluconeogenesis. It catalyzes the conversion of oxaloacetate to phosphoenolpyruvate (see Fig. 76–3). PEPCK deficiency has been described both as a mitochondrial enzyme deficiency and as a cytosolic enzyme deficiency.

The disease has been reported in only six cases. The clinical features are heterogeneous, with hypoglycemia, lactic acidemia, hepatomegaly, hypotonia, developmental delay, and failure to thrive as the major manifestations. Hepatic and renal dysfunction may be present. The diagnosis is based on the reduced activity of PEPCK in liver, fibroblasts, or lymphocytes. Fibroblasts and lymphocytes are not suitable for diagnosing the cytosolic form of PEPCK deficiency because these tissues possess only mitochondrial PEPCK.

Disorders of Pyruvate Metabolism

Pyruvate is metabolized through four main enzyme systems: lactate dehydrogenase, alanine aminotransferase, pyruvate carboxylase, and pyruvate dehydrogenase complex. Deficiency of the M subunit of lactate dehydrogenase causes exercise intolerance and myoglobinuria (see Chapter 76.1). Genetic deficiency of alanine aminotransferase has not been reported in humans.

Disorders of Pyruvate Dehydrogenase Complex Deficiency

The pyruvate dehydrogenase complex (PDHC) catalyzes the oxidation of pyruvate to acetyl CoA, which enters the tricarboxylic

acid cycle for ATP production. The complex comprises five components: E_1 , an a ketoacid decarboxylase; E_2 , a dihydrolipoyl transacylase; E_3 , a dihydrolipoyl dehydrogenase; protein X, an extra lipoate-containing protein; and pyruvate dehydrogenase phosphatase (see Fig. 76–3).

Deficiency of any of these components is associated with lactic acidosis and central nervous system dysfunction. The central nervous system dysfunction is because the brain obtains its energy primarily from oxidation of glucose.

The E_1 defects are caused by mutations in the gene coding for E_1 a subunit, which is X-linked.

Clinical Manifestations.

The disease has a wide spectrum of presentations from the most severe neonatal presentation to a mild late-onset form. The neonatal onset is associated with lethal lactic acidosis, white matter cystic lesions, agenesis of the corpus callosum, and the most severe enzyme deficiency. Infantile onset may be lethal or associated with psychomotor retardation and chronic lactic acidosis, cystic lesions in the brainstem, and basal ganglia pathologic features resembling *Leigh disease*. Older children, usually boys, may have less acidosis, greater enzyme activity, and manifest ataxia with high-carbohydrate diets. Intelligence may be normal. Patients of all ages may have facial dysmorphologic features similar to those of fetal alcohol syndrome.

The E_2 and protein X-lipoate defects are rare and result in severe psychomotor retardation. The E_3 lipoyl dehydrogenase defect leads to deficient activity not only in the pyruvate dehydrogenase complex but also in the a-ketoglutarate and branched-chain ketoacid dehydrogenase complexes. Pyruvate dehydrogenase phosphatase deficiency has also been reported. These other PDHC defects have clinical manifestations within the variable spectrum associated with PDHC deficiency due to E_1 deficiency.

Treatment.

The general prognosis is poor except in rare cases in which mutation is associated with altered affinity for thiamine pyrophosphate, which may respond to thiamine supplementation. Because carbohydrates may aggravate lactic acidosis, a ketogenic diet is rational. The diet has lowered the blood lactate level, but limited or no long-term benefit is seen. A potential treatment strategy is to maintain any residual PDHC in its active form by dichloroacetate, an inhibitor of E_1 kinase. Beneficial effects in some patients have been shown. Patients usually respond to a daily dose of 25–100?mg/kg by oral or intravenous (50?mg/kg × 1 may produce a response within 24?hr) routes.

Deficiency of Pyruvate Carboxylase

Pyruvate carboxylase catalyzes the conversion of pyruvate to oxaloacetate as the first step for gluconeogenesis. Clinical manifestations of this deficiency have varied from neonatal severe lactic acidosis accompanied by hyperammonemia, citrullinemia, and hyperlysinemia (type B) to late-onset mild to moderate lactic acidosis and developmental delay (type A). In both types, patients who survived usually had severe psychomotor retardation with seizures, spasticity, and microcephaly. Some patients have pathologic changes in the brainstem and basal ganglia that resemble *Leigh disease*. The clinical severity appears to correlate with the level of the residual enzyme activity. Laboratory findings are characterized by elevated levels of blood lactate, pyruvate, and alanine; in the case of type B, blood ammonia, citrulline, and lysine levels are also elevated, which might suggest a primary defect of the urea cycle. The mechanism is likely caused by depletion of oxaloacetate, which leads to reduced levels of aspartate, which is a substrate for argininosuccinate synthetase in the urea cycle (see Chapter 74.11). Aspartate and citrate supplements restore the metabolic abnormalities; however, whether this treatment can prevent the neurologic deficits is not known. Diagnosis of pyruvate carboxylase deficiency is made by the measurement of enzyme activity in liver or cultured skin fibroblasts.

Deficiency of Pyruvate Carboxylase Secondary to Deficiency of Holocarboxylase Synthetase or Biotinidase

Deficiency of either holocarboxylase synthetase or biotinidase, which are enzymes of biotin metabolism, results in a secondary deficiency of pyruvate carboxylase (and other biotin-requiring carboxylases and metabolic reactions) and in *clinical manifestations* associated with the respective deficiencies, as well as rash, lactic acidosis, and alopecia (see also Chapter 74.6). The course of holocarboxylase synthetase or biotinidase deficiency can be protracted, with intermittent exacerbation of chronic lactic acidosis, failure to thrive, seizures, and hypotonia leading to spasticity, lethargy, coma, and death. Late-onset milder forms have also been reported. *Laboratory findings* include metabolic acidosis and abnormal organic acids in the urine. *Diagnosis* can be made in skin fibroblasts or lymphocytes by assay for holocarboxylase synthetase activity and in the case of biotinidase in the serum by screening blood spot. *Treatment* consists of biotin supplementation, 5–20?mg/day, and is generally effective if treatment is started before the development of brain

damage. Patients identified through newborn screening have been treated with biotin and have remained asymptomatic.

Both enzyme deficiencies are autosomal recessive traits. Holocarboxylase synthetase and biotinidase are located on chromosome 21q22 and 3p25, respectively. Ethnic specific mutations in the holocarboxylase synthetase gene have been identified. Two common mutations (del7/ins3 and R538C) in the biotinidase gene account for 52% of all mutant alleles in symptomatic patients with biotinidase deficiency.

Mitochondrial Respiratory Chain Defects (Oxidative Phosphorylation Disease)

The mitochondrial respiratory chain catalyzes the oxidation of fuel molecules and transfers the electrons to molecular oxygen with concomitant energy transduction into adenosine triphosphate (ATP)—so-called oxidative phosphorylation. The respiratory chain produces ATP from NADH or $FADH_2$ and includes five specific complexes (I: nicotinamide-adenine dinucleotide [NADH]-coenzyme Q reductase; II: succinate-coenzyme Q reductase; III: coenzyme QH_2 cytochrome C reductase; IV: cytochrome C oxidase; V: ATP synthase). Each complex is composed of 9–25 individual proteins and, with the exception of complex II, are encoded by nuclear or mitochondrial DNA (inherited only from the mother by mitochondrial inheritance). Defects in any of these complexes or assembly system produce chronic lactic acidosis presumably due to a change of redox state with increased concentrations of NADH. In contrast to PDHC or pyruvate carboxylase deficiency, skeletal muscle and heart are usually involved in the respiratory chain disorders; and in muscle biopsy, "ragged red fibers" (indicating mitochondrial proliferation) are often seen (see Fig. 76–4). Because of the ubiquitous nature of oxidative phosphorylation, a defect of the mitochondrial respiratory chain accounts for a vast array of clinical manifestations and should be considered in patients in all age groups presenting with multisystem involvement. Some deficiencies resemble Leigh disease, whereas others cause infantile myopathies such as MELAS (mitochondrial encephalopathy, myopathy, lactic acidosis, and strokelike episodes), MERRF (myoclonus epilepsy, with ragged-red fibers), and Kearns-Sayre syndrome (external ophthalmoplegia, acidosis, retinal degeneration, heart block, myopathy, and high cerebrospinal fluid protein) (see also Chapters 591.2 and 602.4). Diagnosis requires measurement of enzyme activities in tissues or analysis of mitochondrial DNA mutation, or both. Treatment remains largely

symptomatic and does not significantly alter the outcome of disease. However, some patients appear to respond to cofactor supplements such as coenzyme Q_{10} .

Leigh Disease (Subacute Necrotizing Encephalopathy)

Leigh disease remains a neuropathologic description characterized by demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain regions. In decreasing order of severity, the affected areas are the basal ganglia, brain stem cerebellum, and cerebral cortex (see also Chapter 591).

Patients with Leigh disease have defects in several enzyme complexes. Dysfunction in cytochrome C oxidase (complex IV) is the most commonly reported defect, followed by NADH-coenzyme Q reductase (complex I), PDHC, and pyruvate carboxylase. Mutations in the nuclear *SURF1* gene, which encodes a factor involved in the biogenesis of cytochrome C oxidase and mitochondrial DNA mutations in the ATPase 6 coding region, are common molecular findings in patients with Leigh disease.

76.5 Deficiency of Xylulose Dehydrogenase (Essential Benign Pentosuria)

Yuan-Tsong Chen

A reducing substance in the urine in an otherwise healthy individual characterizes essential benign pentosuria. Care should be taken not to mistake the reducing substance for glucose. The pentose in the urine reacts with Clinitest but not with glucose oxidase test papers such as Tes-Tape or Clinistix dipsticks.

l-Xylulose dehydrogenase converts l-xylulose (which can arise from d-glucuronate) to xylitol. Xylitol is converted to d-xylulose, which becomes d-xylulose-5-phosphate and enters the pentose phosphate shunt. Deficiency of this enzyme leads to increased concentration of l-xylulose in blood and urine. This rare defect is most common in Jews. No therapy is required.

Pentosuria can be observed in normal individuals if the dietary pentose intake is increased, as with the excessive ingestion of fruit containing pentose. Under these circumstances, there may be urinary excretion of xylose and arabinose up to 200?mg/24?hr in normal individuals.

76.6 Disorders of Glycoprotein Degradation and Structure

Margaret M. McGovern
Robert J. Desnick

The disorders of glycoprotein degradation and structure include several lysosomal storage diseases that result from defects in glycoprotein degradation and congenital disorders of glycosylation previously called the carbohydrate-deficient glycoprotein syndrome, which is pathophysiologically unrelated. Glycoproteins are macromolecules that are composed of oligosaccharide chains linked to a peptide backbone. They are synthesized by two pathways, the glycosyltransferase pathway, which synthesizes oligosaccharides linked *o*-glycosidically to serine or threonine residues, and the dolichol, lipid-linked pathway, which synthesizes oligosaccharides linked *N*-glycosidically to asparagine.

Glycoprotein lysosomal storage diseases result from the deficiency of the enzymes that normally participate in the degradation of oligosaccharides and include sialidosis, galactosialidosis, aspartylglucosaminuria, and a-mannosidosis (see Box 75–1). In some instances, the abnormality that leads to glycoprotein accumulation also results in abnormal degradation of other classes of macromolecules that contain similar oligosaccharide linkages, such as certain glycolipids and proteoglycans (Table 76–2). In these instances, the underlying enzymatic deficiency results in the accumulation of both glycoproteins and glycolipids. The classification of these types of disorders as lipidoses or glycoproteinoses is dependent on the nature of the predominantly stored substance. Glycoprotein disorders are characterized by autosomal recessive inheritance and a progressive disease course with clinical features that may resemble those seen in the mucopolysaccharidoses.

SIALIDOSIS AND GALACTOSIALIDOSIS

Sialidosis and galactosialidosis are autosomal recessive disorders that result from the isolated deficiency of neuraminidase, and the combined deficiencies of neuraminidase and ß-galactosidase, respectively. Neuraminidase cleaves terminal sialyl linkages of several oligosaccharides and glycoproteins. Its deficiency results in the accumulation of oligosaccharides and the urinary excretion of sialic acid terminal oligosaccharides and sialylglycopeptides. Pathologic storage of substrate is seen in many tissues, including liver, bone marrow, and brain. Two different genes may be involved in the expression of the glycoprotein-specific neuraminidase that is deficient in sialidosis patients. The neuraminidase deficiency in one sialidosis patient is a mutation in a structural gene on chromosome 10, whereas the neuraminidase deficiency in a galactosialidosis patient is in a gene located on chromosome 20.

Clinical Manifestations (see Table 75–7).

The clinical phenotype of neuraminidase deficiency is variable and includes type I sialidosis, which usually presents in the 2nd decade of life with myoclonus and a cherry-red spot. Patients typically have gait disturbances, myoclonus, or visual complaints. In contrast, type II sialidosis occurs as congenital, infantile, and juvenile forms. The congenital and infantile forms result from isolated neuraminidase deficiency, whereas the juvenile form results from both neuraminidase and ß-galactosidase deficiency. Hydrops fetalis, neonatal ascites, hepatosplenomegaly, stippling of the epiphyses, periosteal cloaking, and stillbirth or death characterizes the congenital type II disease during infancy. The type II infantile form presents in the 1st yr of life with dysostosis multiplex, moderate mental retardation, visceromegaly, corneal clouding, cherry-red spot, and seizures. The juvenile type II form of sialidosis, which is sometimes designated galactosialidosis, has a variable age at onset ranging from infancy to adulthood. In infancy, the phenotype is similar to that of GM_1 gangliosidosis with edema, ascites, skeletal dysplasia, and a cherry-red spot. Patients with later-onset disease have dysostosis

TABLE 76.6-2 -- **Characteristics of Congenital Disorders of Glycosylation (**

Name	Defect	Dysmorphology	Neurologic Signs	Gastrointest Signs
CDGIa	Phosphomannomutase 2 M6P ? multiplex, visceromegaly, mental retardation, dysmorphism, corneal clouding, progressive neurologic deterioration, and bilateral cherry-red spots.

The *diagnosis* of sialidosis and galactosialidosis is achieved by the demonstration of the specific enzymatic deficiency. Prenatal diagnosis using cultured amniotic cells is possible.

No specific *treatment* exists for any form of the disease.

ASPARTYLGLUCOSAMINURIA

Aspartylglucosaminuria is a rare autosomal recessive lysosomal storage disorder, except in Finland where the carrier frequency is estimated to be 1/36. The disorder results from the deficient activity of aspartylglucosaminidase and the subsequent accumulation of aspartylglucosamine, particularly in the liver, spleen, and thyroid. The gene for the enzyme has been localized to the long arm of chromosome 4. In the Finnish population, a single mutation in the gene (C163S) accounts for most mutant alleles, whereas outside of Finland a large number of private mutations are present. Affected individuals with aspartylglucosaminuria typically present in the 1st yr of life with recurrent infections, diarrhea, and hernias (see Table 75–7). Coarsening of the facies and short stature usually develop later. Other features include joint laxity, macroglossia, hoarse voice, crystal-like lens

opacities, hypotonia, and spasticity. Psychomotor development is usually near normal until the age of 5 yr when a decline is noted. Behavioral abnormalities are typical, and the IQ in affected adults is less than 40. Survival to adulthood is common, with most early deaths attributable to pneumonia or other pulmonary causes. Definitive diagnosis requires measurement of the enzyme in peripheral blood leukocytes. Molecular diagnosis by analysis of DNA for the C163S mutation is possible for Finnish patients. Prenatal diagnosis by the determination of the level of aspartylglucosaminidase in cultured amniocytes or chorionic villi is also possible. No specific treatment is available, and care is supportive. Bone marrow transplantation

has been attempted in several patients with no improvement in neurologic function.

a-MANNOSIDOSIS

a-Mannosidosis is an autosomal recessive disorder that results from the deficient activity of a-mannosidase and the accumulation of mannose-rich compounds. The gene encoding the enzyme is localized to chromosome 19p13.2-q12. Affected patients with this disorder display clinical heterogeneity. There is a severe infantile form, or type I disease, and a milder juvenile variant, type II disease (see Table 75–7). All patients have psychomotor retardation, facial coarsening, and dysostosis multiplex. However, the infantile form of the disorder is characterized by more rapid mental deterioration, with death occurring between the ages of 3 and 10 yr. Patients with the infantile form also have more severe skeletal involvement and hepatosplenomegaly. The juvenile disorder is characterized by onset of symptoms during early childhood or adolescence with milder somatic features and survival to adulthood. Hearing loss, destructive synovitis, pancytopenia, and spastic paraplegia have all been reported in type II patients. The diagnosis is made by the demonstration of the deficiency of a-mannosidase activity in white blood cells or cultured fibroblasts, and prenatal diagnosis is also possible. No specific therapy exists for the disorder, although bone marrow transplantation has been attempted in several patients.

CONGENITAL DISORDERS OF GLYCOSYLATION

The congenital disorders of glycosylation (CDG), previously known as the carbohydrate-deficient glycoprotein syndrome are autosomal recessive disorders that result from defects in the synthesis and transport (CDG type I) or modification and processing (CGD type II) of the carbohydrate moiety of glycoproteins (see Table 76–2). Because this post-translational modification may affect many proteins in many tissues, the disorders are systemic and heterogeneous. Carbohydrate side glycans are needed for secretion and membrane binding of many proteins. A distinctive biochemical marker of all of these disorders is the presence of carbohydrate-deficient transferrin in serum and cerebrospinal fluid as determined by isoelectric focusing electrophoresis (IEF). Each disorder has its own pattern on IEF. Clinical manifestations are usually both neurologic and multivisceral, involving many different tissues (see Table 76–2).

In patients with CDG type I (type Ia is the most common) the *clinical manifestations* in infancy include hypotonia, weakness, hyperreflexia, strokelike episodes, dysmorphic features, and inverted nipples (see Table 76–2). In childhood, ataxia, muscle atrophy, decreased deep tendon reflexes, toe walking, and continued strokelike episodes are observed. The latter events may be related to reduced factor XI, proteins C and S, and antithrombin III. Strabismus is a consistent finding, and retinitis pigmentosa is common. Growth failure, liver dysfunction, retinal degeneration, and skeletal abnormalities have been described. The skeletal features may include contractures, kyphoscoliosis, and pectus carinatum, all of which may be secondary to the neurologic effects of the disorder. Pericardial effusion in older patients and hypertrophic obstructive cardiomyopathy in the infant may occur. Transferrin studies have revealed that infantile olivopontocerebellar atrophy is a severe form of some of the CDG. Lipodystrophy with prominent fat pads on the buttocks and suprapubic area is a distinctive feature. Adults with type Ia have hypogonadism and developmental delay and are nonambulatory. These disorders should be considered in patients with failure to thrive, mental retardation, cerebellar hypoplasia, hypotonia, hepatic dysfunction, and episodic strokelike episodes. In contrast, patients with type Ib disease do not have neurologic symptoms and usually present with hypoglycemia, protein-losing enteropathy, vomiting, and diarrhea. The *diagnosis* can be confirmed by analysis of the transferrin pattern by isoelectric focusing. Distinct transferrin patterns are identified in affected patients corresponding to CDG types I and II. *Treatment* is symptomatic. Oral mannose has been effective only in patients with type Ib CDG.

Chapter 77 - Mucopolysaccharidoses

Robert M. Kliegman
Joseph L. Muenzer

Mucopolysaccharidoses (MPSs) are inheritable storage diseases caused by a deficiency of lysosomal enzymes that degrade glycosaminoglycans (GAGs, previously called *mucopolysaccharides*). The MPSs are a heterogeneous group characterized by the intralysosomal accumulation of GAGs, excessive urinary excretion of GAGs, and variable degrees of progressive mental and physical deterioration and, in severe forms, premature death. Each type has a specific lysosomal enzyme deficiency, and many have variable phenotypic expression with characteristic degrees of organ involvement and rates of deterioration (Table 77–1). Depending on the enzyme deficiency, the metabolism of dermatan sulfate, heparan sulfate, or keratan sulfate may be blocked alone or in combination. Lysosomal accumulation of the GAGs eventually results in cell, vascular, tissue, and organ dysfunction. The MPS disorders share many clinical features, although in variable degrees. These include a chronic and progressive course, multisystem involvement, organomegaly, dysostosis multiplex, and abnormal facial features (Tables 77–1 and 77–2). Vision, hearing, airway and cardiovascular function, and joint mobility may be affected. Mental retardation is a common feature of the severe forms. There is clinical similarity among different enzyme deficiencies and, conversely, a wide spectrum of clinical severity within any enzyme deficiency. MPSs are characterized by autosomal recessive traits, except for MPS II, which is an X-linked recessive condition.

Numerous identified mutations are known for each gene in each disorder. Many patients are compound heterozygotes for rare alleles. Mutation analysis is beneficial in establishing genotype-phenotype correlation in Hurler syndrome and the severe

TABLE 77-1 -- **Classification of the Mucopolysaccharidoses**

Number	Eponym	Enzyme Deficiency	Stored Glycosaminoglycan	Major Clinica Manifestation
MPS I H	Hurler	a-L-Iduronidase	Dermatan sulfate, heparan sulfate	Mental retarda heart disease, corneal cloudi coarse facies, dysostosis mu hepatosplenor cardiac diseas death before 1 age
MPS I S	Scheie	a-L-Iduronidase	Dermatan sulfate, heparan sulfate	Normal intellig and life span, corneal cloudi joints, and hea disease
MPS I H/S	Hurler-Scheie	a-L-Iduronidase	Dermatan sulfate, heparan sulfate	Phenotype intermediate between Hurle Scheie syndro
MPS II	Hunter[*]	Iduronate sulfatase	Dermatan sulfate, heparan sulfate	Wide spectrun severity, mild t severe; dysost multiplex, card disease, ment retardation, co facies, hepatosplenor death before 1 severe form; n intelligence wi variable sever somatic featur the milder forn

TABLE 77-2 -- Management of Mucopolysaccharidosis

Problem	Disorders	Management
Hydrocephalus	MPS I, II, IV	CT scan Ventriculoperitoneal shunting
Corneal clouding	MPS I, IV, VI, VII	Corneal transplant Monitor for glaucoma
Retinal degeneration	MPS I, II, III	Night light
Hearing	Many types	Ventilating tubes, hearing aids
Joint stiffness	Most except MPS IV	Range of motion exercises
Carpal tunnel syndrome	Many types	Routine electromyography Surgical decompression
Obstructive airways (apnea)	Many types	Tonsillectomy and adenoidectomy CPAP at night Laser excision of tracheal lesions Tracheostomy
Anesthesia	MPS I, II, IV, VI	Avoid atlantoaxial subluxation Use small endotracheal tube Anticipate prolonged recovery
Mitral regurgitation	MPS I, II	Valve replacement Endocarditis prevention
Aortic valve disease	MPS I H/S, IS, IV, VI	As above
Spinal cord compression	MPS IV most common Others except MPS III and IX	MRI of cervical spine Surgical stabilization

CPAP = continuous positive airway pressure.

form of MPS II, but for most mutations the clinical phenotype cannot be predicted.

Clinical Manifestations

MUCOPOLYSACCHARIDOSIS I.

Deficiency of iduronidase results in a wide range of clinical involvement from the most severe, Hurler syndrome, to the mild Scheie syndrome, which are ends of a broad clinical spectrum. Hurler syndrome is the prototype for describing MPSs, but this is misleading because it is only representative of the most severe end of a spectrum.

Hurler Syndrome. This form of MPS I is a severe progressive disorder with multiple organ and tissue involvement that results in premature death, usually by 10 yr of age. An infant with Hurler syndrome appears normal at birth. Diagnosis is made between 6–24 mo with evidence of hepatosplenomegaly, skeletal deformity, coarse facial features, corneal clouding, large tongue, prominent forehead, joint stiffness, and short stature. Acute cardiomyopathy may be a feature in some infants younger than 1 yr of age. Most children with Hurler syndrome acquire only limited language skills because of developmental delay, chronic hearing loss, and an enlarged tongue.

Hearing loss is common and is caused by a combination of conductive and neurosensory problems. Most patients have recurrent upper respiratory tract and ear infections, noisy breathing, and persistent copious nasal discharge. Progressive ventricular enlargement with increased intracranial pressure caused by communicating hydrocephalus also occurs. Corneal clouding, glaucoma, and retinal degeneration are common. Obstructive airway disease develops in many patients, necessitating tracheostomy. Obstructive airway disease, respiratory infection, and cardiac complications are the common causes of death.

Radiographic changes represent the many skeletal abnormalities in the MPSs and are known as *dysostosis multiplex*. The skull is large, with thickened calvarium, premature closure of lambdoid and sagittal sutures, shallow orbits, enlarged J-shaped sella, and abnormal spacing of teeth with dentigerous cysts. Anterior hypoplasia of the lumbar vertebrae with kyphosis is seen early. The diaphyses of the long bones are enlarged with an irregular appearance of the metaphyses; the epiphyseal centers are not well developed. The pelvis is usually poorly formed with small femoral heads and coxa valga. The clavicles are short, thickened, and irregular. The ribs have been described as oar-shaped—narrowed at the vertebral ends and flat and broad at their sternal ends. The phalanges are short and trapezoid with widening of the diaphyses.

The gene encoding a-iduronidase is on chromosome 4p16.3 and spans 19?kb and includes 14 exons. Mutation analysis has revealed two major alleles, W402X and Q70X, and a minor allele, P533R, that account for more than half the MPS I alleles in the white population. None of these alleles produce functional enzyme (null alleles) and in homozygosity or compound heterozygosity give rise to Hurler syndrome, the severe form of MPS I. There are numerous mutations that occur in only one or a few individuals.

Hurler-Scheie Syndrome. This classification describes a clinical phenotype that is intermediate between Hurler and Scheie syndromes and is characterized by progressive somatic involvement, including dysostosis multiplex with little or no intellectual dysfunction. The onset of symptoms is usually observed between 3–8 yr; survival to adulthood is common. Cardiac involvement and upper airway obstruction contribute to clinical mortality. Patients have micrognathia and spondylolisthesis, which may cause cord compression.

Scheie Syndrome. This mild form of MPS I is characterized by joint stiffness, aortic valve disease, corneal clouding, and few other somatic features. Onset of significant symptoms is usually after the age of 5 yr, with diagnosis made between 10 and 20 yr. Patients with Scheie syndrome have normal intelligence and stature but have significant joint and ocular involvement. Ophthalmic features include severe corneal clouding, glaucoma, and retinal degeneration. Obstructive airway disease, causing sleep apnea, develops in some patients, necessitating tracheostomy. Aortic valve disease is common and has required valve replacement in some patients.

MUCOPOLYSACCHARIDOSIS II.

Hunter syndrome (MPS II) comprises two recognized clinical entities, severe and mild, that represents two ends of a wide spectrum. The severe and mild forms of Hunter syndrome are separated on clinical grounds because neither has detectable iduronate sulfatase (IDS) activity. The severe form of Hunter syndrome has features similar to those of Hurler syndrome except for the lack of corneal clouding and the slower progression of somatic and central nervous system (CNS) deterioration. The mild form is somewhat analogous to Scheie syndrome, with a prolonged life span, minimal CNS involvement, and slow progression of somatic deterioration. Coarse facial features, short stature, skeletal deformities, joint stiffness, and mental retardation with onset of disease usually between 2–4 yr of age characterize the severe form of Hunter syndrome. Gastrointestinal storage may produce

chronic diarrhea. Communicating hydrocephalus is a common feature of the severe form, which can be difficult to detect because of the concurrent CNS deterioration. Extensive, slowly progressive neurologic involvement similar to the late stages of Sanfilippo syndrome usually precedes death, which usually occurs between 10–15 yr of age.

A milder form of MPS II has been recognized, with preservation of intelligence in adult life but with obvious clinical features of somatic involvement. Somatic features are similar to the severe form of MPS II but occur at a greatly reduced rate of progression. Airway involvement, hearing impairment, carpal tunnel syndrome, and joint stiffness are common and can result in significant loss of function in both the mild and severe forms.

Hunter syndrome is an X-linked disorder. The gene encoding IDS contains nine exons that span 24?kb and is mapped to Xq28. About 20% of patients with the severe form of MPS II have major deletions or rearrangements of the IDS gene. MPS II patients with an unusually severe phenotype have a very large deletion of the IDS locus, including adjoining genes, resulting in a contiguous gene syndrome. Most MPS II mutations are point mutations, small deletions, or insertions, and many occur in only a single family.

MUCOPOLYSACCHARIDOSIS III.

Sanfilippo syndrome makes up a biochemically diverse but clinically similar group of four recognized types. Each type is due to a different enzyme deficiency involved in the degradation of heparan sulfate (see Table 77–1). Phenotypical variations exist in MPS III patients but to a lesser degree than other MPS disorders, possibly because a very mild form of MPS III may be difficult to recognize. Patients with Sanfilippo syndrome are characterized by slowly progressive, severe CNS involvement with mild somatic disease. Such disproportionate involvement of the CNS is unique to MPS III. Onset of clinical features usually occurs between 2–6 yr in a child who previously appeared normal. Presenting features can include delayed development, hyperactivity with aggressive behavior, coarse hair, hirsutism, sleep disorders, and mild hepatosplenomegaly. Delays in diagnosis of MPS III are common secondary to the mild physical features, hyperactivity, and slowly progressive neurologic disease. Severe neurologic deterioration occurs in most patients by 6–10 yr, accompanied by rapid deterioration of social and adaptive skills. Severe behavior problems, including sleep disturbance, uncontrolled hyperactivity, temper tantrums, destructive behavior, and physical aggression, are common. Profound mental retardation and behavior

problems often occur in patients with normal physical strength, making management particularly difficult.

The gene encoding heparan *N*-sulfatase (MPS III A [Sanfilipo A]) spans 11?kb and is localized to chromosome 17q25.3. The gene encoding a-*N*-acetylglucosaminidase (MPS III B [Sanfilipo B]) spans 8.5?kb, comprises six exons, and is localized on chromosome 17q21. Mutations have been found for all the MPS III disorders for which the genes have been isolated. Most MPS III mutations are uncommon, consisting of the missense type, with a few premature terminations and small deletions.

MUCOPOLYSACCHARIDOSIS IV.

Morquio syndrome (MPS IV) is caused by defective degradation of keratan sulfate. Two enzyme deficiencies resulting in Morquio syndrome have a wide spectrum of clinical manifestations. Both types of Morquio syndrome are characterized by significant, short-trunk dwarfism, fine corneal deposits, a skeletal dysplasia that is distinct from other mucopolysaccharidoses, and preservation of intelligence. The dominant clinical features of Morquio syndrome are related to the skeleton and its effects on the CNS. Instability of the odontoid process and ligamentous laxity can result in life-threatening atlantoaxial subluxation. Surgery to stabilize the upper cervical spine, usually by posterior spinal fusion, before the development of cervical myelopathy can be lifesaving. The appearance of genu valgus, kyphosis, growth retardation with short trunk and neck, and waddling gait with a tendency to fall are early symptoms of MPS IV. Extraskeletal manifestations may include mild corneal clouding, hepatomegaly, cardiac valvular lesions, and small teeth with abnormally thin enamel and frequent caries formation. Patients with mild forms of MPS IV have been reported with almost normal stature, mild skeletal anomalies with dysplastic hips, corneal clouding, and absent keratosulfaturia.

The gene encoding *N*-acetylgalactosamine-6-sulfatase (MPS IV A [Morquio A) spans about 50?kb, contains 14 exons, and is on chromosome 16q24.3. About 100 MPS IV A mutations are known, consisting of missense or small deletions. Two mutations are recurring in patients from Northern Ireland and Australia and may explain the relatively high incidence (founder effect) of MPS IV in Northern Ireland. Several missense mutations are described in the ß-galactosidase gene that causes MPS IV B, a rare form of Morquio syndrome.

MUCOPOLYSACCHARIDOSIS VI.

Maroteaux-Lamy syndrome, caused by deficiency of *N*-acetylgalactosamine-4-sulfatase, is characterized by preservation of intelligence but with severe to mild somatic involvement, as seen in MPS I. The somatic involvement of the severe form of MPS IV is characterized by corneal clouding, coarse facial features, joint stiffness, valvular heart disease, communicating hydrocephalus, and dysostosis multiplex. In the severe form, growth can be normal for the first few years of life but seems to virtually stop after age 6–8 yr. The mild to intermediate forms of Maroteaux-Lamy syndrome can be easily confused with Scheie syndrome. Spinal cord compression from thickening of the dura in the upper cervical canal with resultant myelopathy is a frequent occurrence in patients with the milder form of MPS VI.

The gene encoding *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B) is composed of eight exons and has been localized to chromosome 5q13q14. More than 30 mutations are known, most of which are in single families. Mutations found in MPS VI include frameshift, nonsense, and missense mutations.

MUCOPOLYSACCHARIDOSIS VII.

Sly syndrome (MPS VII), resulting from a deficiency of ß-glucuronidase, is the rarest of all forms of MPS but also has the widest range of clinical involvement from a neonatal form to mild disease in adults. A severe neonatal form is characterized by hydrops fetalis, dysostosis multiplex, and clinical and pathologic findings of a lysosomal storage disease. The severe neonatal form of ß-glucuronidase deficiency is one of the few lysosomal storage diseases diagnosable in utero or at birth. The clinical involvement in MPS VII is similar to that seen in MPS I, with coarse facial features, hepatosplenomegaly, umbilical hernias, gibbus, and dysostosis multiplex, with varying degrees of clinical severity and mental retardation. Granulocytes have coarse metachromatic granules.

The gene encoding ß-glucuronidase spans 21?kb, contains 12 exons, and is localized to chromosome 7q21.1. More than 35 mutations are known, mostly missense, but also nonsense, frameshift, and splice site.

MUCOPOLYSACCHARIDOSIS IX.

Clinical findings in one case are bilateral nodular soft tissue periarticular masses, lysosomal storage of GAGs, mildly dysmorphic craniofacial features, short stature, and normal joint movement and intelligence. The clinical findings may be caused by an inability to degrade the hyaluronan (formerly called hyaluronic acid) that is normally found in cartilage and synovial fluid.

Diagnosis.

Analysis of urinary GAGs is an initial diagnostic test. Many methods are available for urinary GAG analysis, ranging from the semiquantitative spot test to more precise qualitative and quantitative analyses. Spot tests are quick, inexpensive, and useful for initial evaluation but are subject to both false-positive and false-negative results, with reliability largely dependent on the testing laboratory. Any individual who is suspected of an MPS disorder based on clinical features, radiographic results, or urinary mucopolysaccharide screening tests should have a

definitive diagnosis established by enzyme assay. Serum, leukocytes, or cultured fibroblasts are used as the tissue source for measuring lysosomal enzymes. The choice of tissue used depends on the particular enzyme and the preference of the laboratory. Prenatal diagnosis is available for all MPSs and is carried out on cultured cells from amniotic fluid or chorionic villus biopsy. Measurement of GAGs in amniotic

fluid is unreliable. Carrier testing is difficult to perform by enzyme analysis. Carrier testing by enzyme analysis in Hunter syndrome, an X-linked disorder, is problematic and is not recommended. Molecular diagnosis is the preferred method of carrier testing provided that the mutation in the family under consideration is known.

Treatment.

Bone marrow transplantation has resulted in significant clinical improvement of somatic disease in MPS I and increased long-term survival. Resolution or improvements have been noted in hepatosplenomegaly, joint stiffness, facial appearance, obstructive sleep apnea, heart disease, communicating hydrocephalus, and hearing loss. However, the skeletal and ocular anomalies are not corrected. Orthopedic procedures, including femoral osteotomies, acetabular reconstruction, and posterior spinal fusion, are necessary for most patients with Hurler syndrome after bone marrow transplantation to maintain function and gait. The neuropsychologic outcomes of MPS vary widely after bone marrow transplantation. Hurler syndrome patients who have undergone transplantation before 24 mo of age and with a baseline mental development index greater than 70 have improved long-term outcome. The microglia cells in the CNS, which are of bone marrow origin, are believed to be the source of the enzyme in the brain after bone marrow transplantation. Preservation of intelligence has not occurred in patients with severe MPS II or MPS III. Bone marrow transplantation is recommended for Hurler syndrome in patients who are younger than 24 mo of age and have no significant neurologic disease at the time of transplantation. Although bone marrow transplantation has significantly modified the natural history of the disease and improved survival in some patients, the procedure is not curative. Somatic disease has generally improved, except for the skeleton and eyes, but neurologic outcomes have varied.

Enzyme replacement using recombinant enzyme is a promising method to treat the somatic features of MPSs. There are ongoing clinical trials of recombinant a-L-iduronidase for MPS I patients. Early results demonstrate normalization of urinary GAG excretion, decreased or normalization of liver and spleen size, improved growth, decreased episodes of sleep apnea, improved joint range of motion, decreased pain, enhanced endurance, and improved activity. Enzyme replacement therapy trials using recombinant enzyme should be initiated in other MPS disorders once adequate quantities of recombinant enzyme are produced. Recombinant enzyme administered peripherally is not expected to cross the blood-brain barrier and improve or stabilize the CNS disease. Complications of enzyme replacement may include antibody formation against the recombinant enzyme and allergic reactions (urticaria).

Because most patients are not candidates for specific therapies at this time, supportive management, with particular attention to respiratory and cardiovascular complications, hearing loss, carpal tunnel syndrome, spinal cord compression, and hydrocephalus, can greatly improve the quality of life for patients and their families (see Table 77–2). The progressive nature of clinical involvement in MPS patients dictates the need for specialized and coordinated evaluation of their clinical status on a regular basis.

Chapter 78 - Disorders of Purine and Pyrimidine Metabolism

James C. Harris

Purines provide the primary source of cellular energy through adenosine triphosphate (ATP) and, together with pyrimidines, provide the source for the RNA and DNA that stores, transcribes, and translates genetic information. Purines also provide the basic coenzymes (nicotinamide-adenine dinucleotide [NAD] and its reduced form [NADH]) for metabolic regulation and play a major role in signal transduction and translation (guanosine triphosphate [GTP], cyclic adenosine monophosphate [AMP], cyclic guanosine monophosphate [GMP]). Metabolically active nucleotides are formed from heterocyclic nitrogen-containing purine bases (guanine and adenine) and pyrimidine bases (cytosine, uridine, and thymine). The early steps in the biosynthesis of the purine ring are shown in Figure 78–1 . Purines are primarily produced from endogenous sources; dietary purines usually have a small role. The end product of purine metabolism in humans is uric acid (2,6,8-trioxypurine).

The inherited disorders of purine and pyrimidine metabolism cover a broad spectrum of illnesses with various presentations. These include hyperuricemia, acute renal failure, gout, unexplained neurologic deficits (seizures, muscle weakness, choreoathetoid and dystonic movements), developmental disability, mental retardation, compulsive self-injury and aggression, autistic-like behavior, unexplained anemia, failure to thrive, susceptibility to recurrent infection (immune deficiency), and deafness.

Figure 78-1 Early steps in the biosynthesis of the purine ring.

Although uric acid is not a specific disease marker, increased serum levels in children should always lead to the investigation of the cause of its elevation. The level of uric acid present at any time depends on the size of the purine nucleotide pool derived from de novo purine synthesis, catabolism of tissue nucleic acids, and increased turnover of preformed purines. Uric acid is poorly soluble and must be

excreted continuously to avoid toxic accumulations in the body. Its renal excretion involves the following components: (1) glomerular filtration, (2) reabsorption in the proximal convoluted tubule, (3) secretion near the terminus of the proximal tubule, and (4) limited reabsorption near these secretory sites. Thus, renal loss of uric acid is a result of renal tube excretion and is a function of serum uric acid concentration and a homeostatic mechanism to avoid hyperuricemia. Serum uric acid levels are a less reliable indicator of uric acid production in children than in adults, and, consequently, measurement of the level in urine may be required to determine excessive production in children. Clearance of a smaller portion of uric acid is via the gastrointestinal tract (biliary and intestinal secretion). Because of the poor solubility of uric acid under normal circumstances, uric acid is near the maximal tolerable limits, and small alterations in production or solubility or changes in secretion may result in high serum levels. In renal insufficiency, urate excretion is increased by residual nephrons and by the gastrointestinal tract. Increased production of uric acid is found in malignancy; Reye syndrome; Down syndrome; psoriasis; sickle cell anemia; cyanotic congenital heart disease; pancreatic enzyme replacement; glycogen storage disease types I, III, IV, and V; hereditary fructose intolerance; acyl-coenzyme A dehydrogenase deficiency; and gout.

The *metabolism* of both purines and pyrimidines can be divided into two biosynthetic pathways and a catabolic pathway. The first involves a multistep biosynthesis from precursors through the de novo pathway that leads to the production of purine and pyrimidine nucleotides from ribose-5-phosphate or carbamyl phosphate, respectively. The second is a single-step salvage pathway that recovers purine and pyrimidine bases derived from either dietary intake or the catabolic pathway (Figs. 78–1 , 78–2 , and 78–3). In the de novo pathway, the nucleosides guanosine, adenosine, cytidine, uridine, and thymidine are formed by the addition of ribose-1-phosphate to the purine bases guanine or adenine and to the pyrimidine bases cytosine, uracil, and thymine. The phosphorylation of these nucleosides produces monophosphate, diphosphate, and triphosphate nucleotides. Under usual circumstances, the salvage pathway predominates over the biosynthetic pathway. Synthesis is most active in tissues with high rates of cellular turnover, such as gut epithelium, skin, and bone marrow. The third pathway is catabolism. The end product of the catabolic pathway of the purines is uric acid, whereas catabolism of pyrimidines produces citric acid cycle intermediates. Only a small fraction of the purines turned over each day are degraded and excreted.

Inborn errors in the *synthesis* of purine nucleotides include (1) phosphoribosylpyrophosphate synthetase superactivity and (2) adenylosuccinase deficiency. Disorders resulting from abnormalities in purine *catabolism* include (3) muscle AMP deaminase deficiency, (4) adenosine deaminase deficiency, (5) purine nucleoside phosphorylase deficiency, and (6) xanthine oxidoreductase deficiency. Disorders resulting from the purine *salvage* pathway include (7) hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency and (8) adenine phosphoribosyltransferase (APRT) deficiency.

Inborn errors of pyrimidine metabolism include (1) hereditary orotic aciduria (uridine monophosphate synthase deficiency), (2) dihydropyrimidine dehydrogenase deficiency, (3) dihydropyrimidinase deficiency, (4) ß-ureidopropionase deficiency, (5) pyrimidine 5'-nucleotidase deficiency, (6) pyrimidine 5'-nucleotidase superactivity, and (7) thymidine phosphorylase deficiency.

GOUT

Gout presents as hyperuricemia, uric acid nephrolithiasis, and acute inflammatory arthritis. Gouty arthritis is due to monosodium urate crystal deposits that result in inflammation in joints and surrounding tissues. The presentation is most commonly monoarticular, typically in the metatarsophalangeal joint of the big toe. Tophi, deposits of monosodium urate crystals, may occur over points of insertion of tendons at the elbows, knees, and feet or over the helix of the ears. *Primary gout*,

Figure 78-2 Pathways in purine metabolism and salvage.

ordinarily occurring in middle-aged men, results from the overproduction, decreased renal excretion, or both, of uric acid. Its biochemical etiology is unknown for most of those affected, and it is considered to be a polygenic trait. When hyperuricemia and gout occur in childhood, it is most often *secondary gout*, the result of another disorder in which there is rapid tissue breakdown or cellular turnover leading to increased production or decreased excretion of uric acid. Gout occurs in any condition that leads to reduced clearance of uric acid: during therapy for malignancy or with dehydration, lactic acidosis, ketoacidosis, starvation, diuretic therapy, and renal failure. Excessive purine, alcohol, or carbohydrate ingestion may increase uric acid levels.

Gout is associated with hereditary disorders in three different enzyme disorders that result in hyperuricemia. These include the severe form of HPRT deficiency (Lesch-Nyhan syndrome), partial HPRT deficiency, superactivity of PP-ribose-P synthetase, and glycogen storage disease, type I (glucose-6-phosphatase deficiency) (see Chapter 76.1). In the first two, the basis of hyperuricemia is purine nucleotide and uric acid overproduction, whereas in the third it is both excessive uric acid production and impaired uric acid secretion. Glycogen storage disease types III, V, and VII are associated with exercise-induced hyperuricemia, the consequence of rapid ATP utilization and failure to regenerate it effectively during exercise (see Chapter 76.1).

Familial juvenile gout or familial juvenile hyperuricemic nephropathy (FJHN) is associated with severe renal hypoexcretion of uric acid. Although patients most commonly present from puberty up to the 3rd decade, it has been reported in infancy. It is characterized by hyperuricemia, gout, familial renal disease, and low urate clearance relative to glomerular filtration rate. Familial juvenile hyperuricemic nephropathy is an autosomal dominant disorder, unlike the three inherited purine disorders that are X-linked and the recessively inherited glycogen storage disease. Linkage to 16p12 has been reported in one study of an affected family. It occurs in both males and females and is frequently associated with a rapid decline in renal function that may lead to death unless diagnosed and treated early. Once familial juvenile hyperuricemic nephropathy is recognized, presymptomatic detection is of critical importance to identify asymptomatic family members with hyperuricemia and

to begin treatment, when indicated, to prevent nephropathy.

Treatment of hyperuricemia involves the combination of allopurinol (a xanthine oxidase inhibitor) to decrease uric acid production, probenecid to increase uric acid clearance in those with normal renal function, alkalinization of the urine to increase the solubility of uric acid, and increased fluid intake to reduce the concentration of uric acid. A low purine diet, weight reduction, and reduced alcohol intake are recommended.

ABNORMALITIES IN PURINE SALVAGE

Lesch-Nyhan Syndrome

Lesch-Nyhan syndrome (LNS) is a rare X-linked disorder of purine metabolism that results from HPRT deficiency. This enzyme is normally present in each cell in the body, but its highest concentration is in the brain, especially in the basal ganglia. Manifestations include hyperuricemia, mental retardation, cerebral palsy with early choreoathetosis and later spasticity and dystonia, dysarthric speech, and compulsive self-biting, usually beginning with the eruption of teeth.

Figure 78-3 Pathways in pyrimidine biosynthesis.

There are several clinical presentations of HPRT deficiency. HPRT levels are related to the extent of motor symptoms, to the presence or absence of self-injury, and possibly to the level of cognitive function. The majority of individuals with classic LNS have low or undetectable levels of the HPRT enzyme. Partial deficiency in HPRT (Kelley-Seegmiller syndrome) with more than 1.5–2.0% enzyme is associated with hyperuricemia and variable neurologic dysfunction (neurologic HPRT deficiency). HPRT deficiency with levels over 8% leads to a severe form of gout, with apparently normal cerebral functioning (HPRT-related hyperuricemia), although cognitive deficits may occur. Qualitatively similar cognitive deficit profiles have been reported in both LNS and variant cases. Variants have scores that are intermediate between those of patients with LNS and normal controls on nearly every neuropsychological measure tested.

Genetics.

The *HPRT* gene has been localized to the long arm of the X chromosome (q26-q27). The complete amino acid sequence for *HPRT* is known (approximately 44?kb, 9 exons). The disorder appears in males; occurrence in females is extremely rare and ascribed to nonrandom inactivation of the X chromosome. Absence of *HPRT* prevents the normal metabolism of hypoxanthine, resulting in excessive uric acid production and manifestations of gout, necessitating specific drug treatment (allopurinol). Because of the enzyme deficiency, hypoxanthine accumulates in the cerebrospinal fluid, but uric acid does not; uric acid is not produced in the brain and does not cross the blood-brain barrier. The behavior disorder is not caused by hyperuricemia or excess hypoxanthine because patients with partial HPRT deficiency, the variants with hyperuricemia, do not self-injure and infants having isolated hyperuricemia from birth do not develop self-injurious behavior.

The prevalence of classic LNS has been estimated at 1 in 100,000 to 1 in 380,000 based on the number of known cases in the United States. The incidence of partial variants is not known. Those with the classic syndrome rarely survive the 3rd decade because of renal or respiratory compromise. The life span may be normal for patients with partial HPRT deficiency without severe renal involvement.

Pathology.

MRI demonstrates reductions in the volume of basal ganglia nuclei. Abnormalities in neurotransmitter metabolism have been identified in three autopsied cases with very low HPRT levels. There was a functional loss of 65–90% of the nigrostriatal and mesolimbic dopamine terminals, although the cells of origin in the substantia nigra did not show dopamine reduction. The brain regions primarily involved were the caudate nucleus, putamen, and nucleus accumbens. The neurochemical changes may be linked to functional abnormalities, possibly resulting from a diminution of arborization or branching of dendrites rather than cell loss. A neurotransmitter abnormality is demonstrated by changes in cerebrospinal fluid neurotransmitters and their metabolites and confirmed by positron emission tomography scans of dopamine function. Reductions in vivo in the presynaptic dopamine transporter have been documented in the caudate and putamen.

The mechanism whereby HPRT leads to the neurologic and behavioral symptoms is unknown. However, both hypoxanthine and guanine metabolism is affected and guanine triphosphate (GTP) and adenosine have substantial effects on neural tissues. There is a functional link between purine nucleotides and the dopamine system that involves guanine, the precursor of GTP. Dopamine binding to its receptor results in either an activation (D_1 receptor) or an inhibition (D_2 receptor) of adenylcyclase. Both receptor effects are mediated by G proteins (GTP-binding proteins) dependent on guanine diphosphate (GDP) in the GDP/GTP exchange for cellular activation. Dopamine and adenosine systems are also linked through the role of adenosine as a neuroprotective agent in preventing neurotoxicity. Adenosine agonists mimic the biochemical and behavioral actions of dopamine antagonists, whereas adenosine receptor antagonists act as functional dopamine agonists. Dopamine reduction in brain is documented in HPRT-deficient strains of mutant mice.

Clinical Manifestations.

At birth, infants with LNS have no apparent neurologic dysfunction. After several months, developmental retardation and neurologic signs become apparent. Before the age of 4 mo, hypotonia, recurrent vomiting, and difficulty with secretions may be noted. By 8–12 mo, extrapyramidal signs appear, including chorea and dystonia. By approximately 12 mo, in a significant number of cases, pyramidal tract signs may become evident with hyperreflexia, sustained ankle clonus, positive Babinski sign,

and scissoring. Spasticity may become apparent at this time or, in some instances, later in life.

Cognitive function is usually reported to be in the mild-to-moderate range of mental retardation, although some individuals test in the low normal range. Because test scores may be influenced by difficulty in testing the subjects owing to their movement disorder and dysarthric speech, overall intelligence may be underestimated.

The age at onset of self-injury may be as early as 1 yr and occasionally as late as the teens. Self-injury occurs, although all sensory modalities, including pain, are intact. The self-injurious behavior usually begins with self-biting, although other patterns of self-injurious behavior emerge with time. Most characteristically, the fingers, mouth, and buccal mucosa are mutilated. Self-biting is intense and causes tissue damage and may result in the amputation of fingers and substantial loss of tissue around the lips. Extraction of primary teeth may be required. The biting pattern can be asymmetric, with preferential mutilation of the left or right side of the body. The type of behavior is different from that seen in other mental retardation syndromes involving self-injury where self-hitting and head banging are the most common initial presentations. The intensity of the self-injurious behavior generally requires that the patient be restrained. When restraints are removed, the individual with LNS may appear terrified and stereotypically place a finger in the mouth. The patient may ask for restraints to prevent elbow movement; when the restraints are placed or replaced, he may appear relaxed and more good humored. Dysarthric speech may cause interpersonal communication problems; however, the higher-functioning children can express themselves fully and participate in verbal therapy.

The self-mutilation presents as a compulsive behavior that the child tries to control but frequently is unable to resist. Older individuals may enlist the help of others and notify them when they are comfortable enough to have restraints removed. In some instances, the behavior may be followed by deliberate self-harm. The individual with LNS may also show compulsive aggression and inflict injury to others through pinching, grabbing, or hitting or by using verbal forms of aggression. Afterward the person may apologize, stating that this behavior was out of his or her control. Other maladaptive behaviors include head or limb banging, eye poking, and psychogenic vomiting.

Diagnosis.

The presence of dystonia along with self-mutilation of the mouth and fingers suggests LNS. With partial HPRT deficiency, recognition is linked to either hyperuricemia alone or hyperuricemia and a dystonic movement disorder, but there is no self-injurous behavior. Serum levels of uric acid that exceed 4–5?mg uric acid/dL and a urine uric acid:creatinine ratio of 3:4 or more are highly suggestive of HPRT deficiency, particularly when associated with neurologic symptoms. The definitive diagnosis requires an analysis of the HPRT enzyme in an erythrocyte lysate. Individuals with classic LNS have near 0% enzyme activity, and those with partial variants show values between 1.5% and 60%. The intact cell HPRT assay in skin fibroblasts offers a good correlation between enzyme activity and the severity of the disease. Molecular techniques are used for gene sequencing and the identification of carriers.

Differential diagnosis includes other causes of infantile hypotonia and dystonia. Children with LNS are often initially incorrectly diagnosed as having athetoid cerebral palsy. When a diagnosis of cerebral palsy is suspected in an infant with a normal prenatal, perinatal, and postnatal course, LNS should be considered. Partial HPRT deficiency may be associated with acute renal failure in infancy; therefore, clinical awareness of partial HPRT deficiency is of particular importance.

An understanding of the molecular disorder has led to effective drug treatment for uric acid accumulation and arthritic tophi, renal stones, and neuropathy. Reduction in uric acid alone does not influence the neurologic and behavioral aspects of LNS. Despite treatment from birth for uric acid elevation, behavioral and neurologic symptoms are unaffected. The most significant complications of LNS are renal failure and self-mutilation.

Treatment.

Medical management of this disorder focuses on the prevention of renal failure by pharmacologic treatment of hyperuricemia with allopurinol, efforts to reduce self-mutilation through behavior management and psychosocial support, and the use of restraints or removal of teeth or both. Pharmacologic approaches to decrease anxiety and spasticity with medication have mixed results. Drug therapy focuses on symptomatic management of anticipatory anxiety, mood stabilization, and reduction of self-injurious behavior. Although there is no standard drug treatment, diazepam may be helpful for anxiety symptoms, risperidone for aggressive behavior, and carbamazepine or gabapentin for mood stabilization. Each of these medications may reduce self-injurious behavior by helping to reduce anxiety and/or stabilize mood.

Bone marrow transplantation, which is based on the possibility that the central nervous system damage is produced by a circulating toxin, has been carried out in several patients. Several infant patients have died of complications of bone marrow transplantation. In one adult case in which the transplantation was successful, there was no change in neurologic symptoms or in behavior. In this case, dopamine receptors measured by positron emission tomography before and after the bone marrow transplantation showed no changes in receptor density. There is no evidence that bone marrow transplantation is a beneficial treatment approach. Two patients received partial exchange transfusions every 2 mo for 3–4 years. Erythrocyte hypoxanthine-guanine phosphoribosyltransferase activity was 10–70% of normal during this period, but no reduction of neurologic or behavioral symptoms was apparent. Successful preimplantation genetic diagnosis and in vitro fertilization for LNS has been reported with the birth of an unaffected male infant.

Both the motivation for self-injury and its biologic basis must be addressed in treatment programs. Behavioral techniques alone, using operant conditioning approaches, have not proved to be an adequate general treatment. Although behavioral procedures have had some selective success in reducing self-injury, generalization outside the experimental setting limits this approach and patients under stress may revert to their previous self-injurious behavior. Behavioral approaches may also focus on reducing the self-injurious behavior through the treatment of phobic anxiety associated with being unrestrained. The most common techniques are systematic desensitization, extinction, and differential reinforcement

of other (competing) behavior. Stress management has been recommended to assist patients to develop more effective coping mechanisms. Individuals with LNS do not respond to contingent electric shock or similar aversive behavioral measures. An increase in self-injury may be observed when aversive methods are utilized.

Restraint (day and night) and dental procedures are used to prevent self-injury. The time in restraints is linked to the age at onset of self-injury. Children with LNS can participate in making decisions regarding restraints and the type of restraints. The time in restraints may potentially be reduced with systematic behavior treatment programs. Many patients have teeth

extracted to prevent self-injury. Others use a protective mouthguard designed by a dentist. Most parents suggest that stress reduction and awareness of the patient's needs are the most effective in reducing self-injury. Parents reported that they deal with self-injury by attending to physical comfort and adjusting restraints, talking to the child, and finding something more interesting to do. Positive behavioral techniques of reinforcing appropriate behavior are rated effective by almost half of the families. The use of anticonvulsants as mood stabilizers appears promising, but it requires further study.

Adenine Phosphoribosyltransferase Deficiency

Adenine phosphoribosyltransferase (APRT) catalyzes the synthesis of AMP from adenine and 5-phosphoribosyl-1-pyrophosphate (PP-ribose-P). The absence of this enzyme results in the inability to utilize adenine and in the accumulation of 2,8-dihydroxyadenine, which is extremely insoluble. APRT deficiency is present from birth, becoming apparent as early as 5 mo and as late as the 7th decade. *Clinical manifestations* include urinary calculus formation with crystalluria, urinary tract infections, hematuria, renal colic, dysuria, and acute renal failure. The renal calculi, composed of 2,8-dihydroxyadenine, are radiolucent, soft, and easily crushed. These stones are not distinguishable from uric acid stones by routine tests but require confirmation from the ultraviolet (UV) and infrared (IR) spectrums, mass spectroscopy (MS), x-ray crystallography, or capillary electrophoresis for diagnosis. The presence of brownish spots on the infant's diaper or of yellow-brown crystals in the urine is suggestive.

The enzyme deficiency causes suppression of the salvage of adenine from nutritional sources and the polyamine pathway, with adenine being oxidized by xanthine dehydrogenase into 2,8-dihydroxyadenine. Urinary levels of adenine, 8-hydroxyadenine, and 2,8-dihydroxyadenine are elevated, whereas plasma uric acid is normal. The deficiency may be complete (type I) or partial (type II); the partial deficiency is reported in Japan. The diagnosis is made based on the level of residual enzyme in erythrocyte lysates. The disorder is an autosomal recessive trait with considerable clinical heterogeneity. The *APRT* gene is located on chromosome 16q (16q24.3) and encompasses 2.8?kb of genomic DNA. Because identification of 2,8-dihydroxyadenine is complex, the most common diagnostic test is the measurement of APRT activity in erythrocyte lysates.

Treatment includes high fluid intake, dietary purine restriction, and allopurinol, which inhibits the conversion of adenine to its metabolites, further 2,8-dihydroxyadenine excretion, and further stone formation. Alkalinization of the urine is to be avoided, because, unlike that of uric acid, the solubility of 2,8-dihydroxyadenine does not increase up to pH 9. Shock-wave lithotripsy can be successful. The prognosis depends on renal function at the time of diagnosis. Early treatment is critical in the prevention of stones because severe renal insufficiency may accompany late recognition.

DISORDERS LINKED TO PURINE NUCLEOTIDE SYNTHESIS

Phosphoribosylpyrophosphate Synthetase Superactivity

Phosphoribosylpyrophosphate is a substrate involved in the synthesis of essentially all nucleotides and important in the regulation of the de novo pathways of purine and pyrimidine nucleotide synthesis. Phosphoribosylpyrophosphate synthetase, (PRS) superactivity is inherited as an X-linked trait and presents as two clinical phenotypes with varying degrees of severity. Three distinct PRS cDNAs are known. Two forms are X linked to Xq22-q24 and Xp22.2-p.22.3, respectively, and are widely expressed; the third maps to human chromosome 7 and appears to be transcribed only in the testes. *Clinical manifestations* in the more severe type in affected hemizygous males include signs of uric acid overproduction that are apparent in infancy or early childhood, neurodevelopmental abnormalities, and sensorineural deafness. Hypotonia, delays in motor milestones, ataxia, and autistic-like behavior occur. Blood uric acid may be two to three times normal values, and the urinary excretion of uric acid is increased. Heterozygous female carriers may also develop gout and hearing impairment. The late juvenile to early adult onset type is found in males who show gout or uric acid urolithiasis but no neurologic signs.

This enzyme produces PRPP from ribose-5-phosphate and ATP, as shown in Figures 78–1 and 78–2 . PRPP is the first intermediary compound in the de novo synthesis of purine nucleotides that lead to the formation of inosine monophosphate. Superactivity of the enzyme results in an increased generation of PRPP. Because PRPP amidotransferase, the first enzyme of the de novo pathway, is not physiologically saturated by PRPP, the synthesis of purine nucleotides increases, and, consequently, the production of uric acid is increased. A mechanism for the neurologic symptoms is unknown. The *diagnosis* requires kinetic studies of the enzyme performed in erythrocytes and cultured fibroblasts. This disorder must be differentiated from partial HPRT deficiency involving the salvage pathway, which also results in neurologic HPRT deficiency or hyperuricemia without neurologic features.

Treatment is with allopurinol, which inhibits xanthine oxidase, the last enzyme of the purine catabolic pathway. Uric acid production is reduced and is replaced by hypoxanthine, which is more soluble, and xanthine, which is slightly more soluble than uric acid. The initial dose of allopurinol is 10–20?mg/kg/24?hr in children and is adjusted to maintain normal uric acid levels in plasma. Occasionally, xanthine calculi may form. Consequently, a low purine diet (one free of organ meats, dried beans, and sardines), high fluid intake, and alkalinization of the urine to establish a urinary pH of 6.0–6.5 is necessary. These measures control the hyperuricemia and urate

neuropathy but do not affect the neurologic symptoms.

Adenylosuccinate Lyase Deficiency

Adenylosuccinase lyase (ADSL) catalyzes two pathways in de novo synthesis and purine nucleotide recycling. These are the conversion of succinylaminoimidazole carboxamide ribotide (SAICAR) into aminoimidazole carboxamide ribotide (AICAR) in the de novo synthesis of purine nucleotides and the conversion of adenylosuccinate (S-AMP) into adenosine monophosphate (AMP), the second step in the conversion of inosine monophosphate (IMP) into AMP, in the purine nucleotide cycle. ADSL deficiency results in the accumulation in urine, cerebrospinal fluid, and, to a smaller extent, in plasma, of SAICA riboside (SAICAr) and succinyladenosine (S-Ado), dephosphorylated derivatives of SAICAR and S-AMP, respectively. This is an autosomal recessive disorder; the gene is on chromosome 22q13.1-q13.2; about 20 gene mutations are known. *Clinical manifestations* include varying degrees of psychomotor retardation, generally accompanied by a seizure disorder and/or autistic-like behaviors (poor eye contact and repetitive behaviors). Other patients demonstrate moderate to severe mental retardation sometimes associated with growth retardation and muscle hypotonia. One reported case, a girl, tested in the mild range of mental retardation. Type I has profound mental retardation; cases with mild mental retardation are type II. Other patients have an intermediate clinical symptom pattern with moderately delayed psychomotor development, seizures, stereotypes, and agitation. CT and MRI of the brain may show hypotrophy or hypoplasia of the cerebellum, particularly the vermis. Symptoms may be caused by the neurotoxic effects of accumulating succinyl purines. The ratio of S-Ado/SAICAr is linked to phenotype severity, suggesting that SAICAr is the more toxic compound and that S-Ado might be neuroprotective. The *diagnosis* is based on the presence in urine and cerebrospinal fluid of SAICA riboside and S-ADO, both

normally undetectable. No successful *treatment* has been demonstrated for this disorder. Prenatal diagnosis is possible. Systematic screening is suggested in infants and children with unexplained psychomotor retardation and/or seizures.

DISORDERS RESULTING FROM ABNORMALITIES IN PURINE CATABOLISM

Myoadenylate Deaminase Deficiency (Muscle Adenosine Monophosphate Deaminase Deficiency)

Myoadenylate deaminase is a muscle-specific isoenzyme of AMP deaminase that is active in skeletal muscle. During exercise, the deamination of AMP leads to increased levels of IMP and ammonia in proportion to the work performed by the muscle. Two forms of myoadenylate deaminase deficiency are known: (1) an inherited (primary) form that may be asymptomatic or associated with cramps or myalgia with exercise and (2) a form that may be associated with other neuromuscular or rheumatologic disorders. *Clinical manifestations* include isolated muscle weakness, fatigue, myalgias following moderate-to-vigorous exercise, or cramps. Myalgias may be associated with an increased serum creatine kinase level and detectable electromyelographic abnormalities. Muscle wasting or histologic changes on biopsy are absent. The age at onset may be as early 8 mo of life, with about 25% of cases recognized between 2 and 12 years of age. The enzyme defect has been identified in asymptomatic family members. Secondary forms of muscle AMP deaminase deficiency have been identified in Werdnig-Hoffmann disease, Kugelberg-Welander syndrome, polyneuropathies, and amyotrophic lateral sclerosis (see Chapter 603.2). The metabolic disorder involves the purine nucleotide cycle (see Fig. 78–2). Muscle dysfunction in AMP deaminase deficiency may result from impaired energy production during muscle contraction. It is unclear how affected individuals can be asymptomatic. A mutation of liver AMP deaminase has been proposed as a cause of primary gout, leading to overproduction of uric acid.

The inherited form of the disorder is an autosomal recessive trait. *AMP-D1*, the gene responsible for encoding muscle AMP deaminase, is located on the short arm of chromosome 1. This mutant allele is found at high frequency in white populations. The disorder may be screened for by performing an exercise test. The elevation of venous plasma ammonia after exercise that is seen in normal subjects is absent in AMP deaminase deficiency. The final diagnosis is made by histochemical or biochemical assays of a muscle biopsy. In the primary form enzyme levels are below 2% with little or no immunoprecipitable enzyme. Affected individuals are advised to exercise with caution to prevent rhabdomyolysis and myoglobinuria. It has been proposed that enhancing the rate of replenishment of the ATP pool might be beneficial. Using this rationale *treatment* with ribose (2–60?g/24?hr orally, in divided doses) or xylitol, which is converted to ribose, improves endurance and muscle strength in some cases but is ineffective in others. Genetic approaches may be feasible in the future for inherited cases whereas treatment of the underlying condition is essential in secondary cases.

Adenosine Deaminase Deficiency

See Chapter 116.1 .

Purine Nucleoside Phosphorylase Deficiency

See Chapter 116.2 .

Xanthine Oxidoreductase Deficiency

Xanthine oxidoreductase (XOR) is the catalytic enzyme in the final step of the purine catabolic pathway and oxidates hypoxanthine to xanthine and xanthine to uric acid. Because XOR exists in two forms, xanthine dehydrogenase and xanthine oxidase, the deficiency is also referred to as xanthine dehydrogenase/xanthine oxidase (XDH/XO) deficiency. Xanthine, the immediate precursor of uric acid, is less soluble than uric acid in urine, and deficiency of the enzyme results in xanthinuria. Xanthine oxidoreductase deficiency may occur in an isolated form (xanthinuria type 1), in a combined form involving xanthine oxidoreductase deficiency and aldehyde oxidase deficiency (xanthinuria type II), or in a combined form with deficiency of both xanthine oxidoreductase and aldehyde oxidase and sulfite oxidase deficiency (molybdenum co-factor deficiency). The isolated form results in an almost total replacement of uric acid by hypoxanthine and xanthine. Patients with the isolated form are usually asymptomatic or have mild symptoms; renal stones, often not visible on radiography, are a risk for renal damage and may appear at any age. Crystalline xanthine deposits in muscle may result in muscle pain after exertion.

Rarely, xanthine stones may develop as a result of allopurinol administration. In type II, the clinical presentation is similar to type 1. Molybdenum co-factor deficiency (failure to synthesize the molybdenum co-factor) involves all three molybdoenzymes and like isolated sulfite oxidase deficiency results in neonatal feeding problems, neonatal seizures, increased or decreased muscle tone, ocular lens dislocation, severe mental retardation, and death in early childhood.

The inheritance of type I and II is autosomal recessive; the human XOR gene is located on chromosome 2p22. In both forms of the deficiency, measuring plasma concentrations of uric acid makes the diagnosis; plasma uric acid is low (<1?mg/dL), and xanthine is elevated in plasma and urine. Urinary uric acid is reduced and is replaced by xanthine and hypoxanthine. In molybdenum co-factor deficiency, there is also an excessive excretion of sulfite and other sulfur-containing metabolites. Enzyme diagnostic measurement requires jejunal or liver biopsy because these are the only human tissues that contain appreciable amounts of xanthine oxoreductase. Sulfite oxidase and the molybdenum co-factor can be measured in liver and fibroblasts. Although the isolated deficiency is generally benign, *treatment* with a low purine diet and increased fluid intake are recommended. Allopurinol has been recommended for those with residual xanthine oxoreductase activity. It completely blocks the conversion of hypoxanthine into the far less soluble xanthine. The prognosis for molybdenum co-factor deficiency is very poor, and drug trials to date have been unsuccessful. This disorder may be a candidate for somatic gene therapy in the future.

DISORDERS OF PYRIMIDINE METABOLISM

The pyrimidines are the building blocks of DNA and RNA and involved in the formation of coenzymes and active intermediates in carbohydrate and phospholipid metabolism. The pyrimidines uracil and thymine are degraded in four steps (see Fig. 78–3). Seven disorders of pyrimidine metabolism are known. The first defect, hereditary orotic aciduria, is in the de novo synthetic pathway, whereas the other disorders involve superactivity (in one syndrome) or defects in the pyrimidine degradation pathway. The first three steps of the degradation pathways for thymine and uracil, respectively, make use of the same enzymes (DPD, DPH, and UP). These three steps result in the conversion into ß-alanine from uracil. Pyrimidines may play an important role in the regulation of the nervous system. Reduced production of the neurotransmitter function of ß-alanine is hypothesized to produce clinical symptoms. These rare disorders may be overlooked because symptoms are not highly specific; however, they should be considered as possible causes of anemia and neurologic disease and are a contraindication for treatment of cancer patients with certain pyrimidine analogues.

Hereditary Orotic Aciduria (Uridine Monophosphate Synthase Deficiency)

Hereditary orotic aciduria is associated with deficient activity of the last two enzymes of the de novo pyrimidine synthetic pathway (orotate phosphoribosyltransferase and orotidine-5'-monophosphate decarboxylase). The activities of these two enzymes reside in separate domains to a single polypeptide coded by a single gene. This bifunctional protein, uridine 5'-monophosphate (UMP) synthase, catalyzes the two-step conversion of orotic acid to UMP. Hereditary orotic aciduria (UMP synthase deficiency) results in the excessive accumulation of orotic acid. *Clinically*, patients with hereditary orotic aciduria have a macrocytic hypochromic megaloblastic anemia that is unresponsive to the usual forms of therapy (iron, folic acid, and B_{12}) and may have leukopenia. If untreated, this disorder can lead to developmental retardation, failure to thrive, cardiac disease, strabismus, and crystalluria. Renal function is generally normal. Heterozygotes may have mild orotic aciduria but are not affected.

This disorder has autosomal recessive inheritance. The gene for uridine monophosphate synthase is located on the long arm of chromosome 3 (3q13). The clinical features may be related to pyrimidine nucleotide depletion. Metabolites derived from several pharmacologic agents (5-azauridine, allopurinol) produce secondary orotic aciduria and orotidinuria by specifically inhibiting orotidine-5'-monophosphate decarboxylase. Genetic metabolic defects that involve four of the six enzymes associated with the urea cycle may result in orotic aciduria secondary to PP-ribose-P depletion resulting from a substantial increased flux through the de novo pathway. Orotic aciduria may also occur in association with parenteral nutrition, essential amino acid deficiency, and Reye syndrome. The enzymatic defect may be demonstrated in liver, lymphoblasts, erythrocytes, leukocytes, and cultured skin fibroblasts. A carrier detection test is available, as is prenatal diagnosis.

The administration of uridine has been an effective *treatment* in most cases and leads to clinical improvement and reduction in orotic acid excretion. Lifelong treatment is required. Uracil is ineffective because, unlike purines, pyrimidine salvage occurs at the nucleoside level. The long-term *prognosis* in uncomplicated cases is good; congenital malformations and other associated features may adversely affect outcome.

Dihydropyrimidine Dehydrogenase Deficiency

Dihydropyrimidine dehydrogenase (DPD) catalyzes the initial and rate-limiting step in the degradation of the pyrimidine bases uracil and thiamine. DPD has been identified in most tissues, with the highest activity being in lymphocytes. DPD deficiency is characterized by a variable phenotype with accumulation of thiamine and uracil in urine, plasma, and cerebrospinal fluid and no activity in fibroblasts. DPD is the initial and rate-limiting enzyme in the catabolism of the neoplastic drug 5-fluorouracil, being responsible for 80% of its catabolism. Patients with a partial deficiency of this enzyme are at risk for developing a severe 5-fluorouracil–associated toxicity. Several clinical forms are described. The *clinical manifestations* in children may include seizure disorder, mental retardation, and motor delay in half of the patients. Less frequent are growth retardation, microcephaly, autistic-like behavior, and ocular anomalies. Others do not show developmental abnormalities but may have milder neurologic symptoms and language disorder. In most cases, there is an initial period of normal psychomotor development, followed by subsequent developmental delays. Symptoms may link to altered uracil, thymine, and ß-alanine homeostasis. In adults, neurotoxicity (headache, somnolence, visual illusions, and memory impairment) is linked to pyrimidinemia after treatment for cancer with 5-fluorouracil.

DPD deficiency is an autosomal recessive disorder mapping to chromosome Ip22 with at least seven known mutations. It is estimated that the frequency of the

heterozygote may be as high as 3%. Prenatal *diagnosis* is possible. Diagnostic tests use high-pressure liquid chromatography (HPLC) or gas chromatography/mass spectroscopy (GC/MS). Alternatively, DPD deficiency may be confirmed by measuring the enzyme in cultured fibroblasts and leukoblasts. Uric acid levels are normal. Because ß-alanine is a structural analogue of ?-aminobutyric acid and glycine, it may affect inhibitory neurotransmission. There is no established *treatment* for this disorder, however; patients with seizures do respond to anticonvulsant medications. Patients with DPD deficiency should not be given 5-fluorouracil; its deficiency should be suspected when neurologic symptoms emerge after cancer treatment with 5-fluorouracil.

Dihydropyrimidinase Deficiency (Dihydropyrimidinuria)

Dihydropyrimidinase (DPH) is the second enzyme in the three-step degradation pathway of uracil and thiamine leading to increased urinary excretion. Dihydropyrimidinase deficiency is characterized by dihydropyrimidinuria and a variable clinical phenotype. *Clinical manifestations* in three unrelated affected cases include seizures with dysmorphic features and developmental delay in two of these cases. Three unrelated infant and two adult asymptomatic cases were identified in a screening program for pyrimidine-degradation disorders in Japan and were asymptomatic despite the accumulation of pyrimidine degradation products in body fluids.

Inheritance is autosomal recessive with the gene mapped to chromosome 8q22. There may be significant difference in residual activity between mutations observed in symptomatic and asymptomatic individuals. Population prevalence in a Japanese sample is 0.1%. Organic acid screening by GC-MS may identify increased amounts of these compounds in urine. Oral loading tests with uracil, dihydrouracil, thymine, and dihydrothymine have been used to differentiate this disorder from DPD deficiency. In symptomatic cases, *treatment* with ß-alanine has been attempted with equivocal results. Increased sensitivity to fluorouracil is expected.

N-Carbamyl-ß-Amino Aciduria (Deficiency of ß-Ureidopropionase)

The pyrimidine bases uracil and thymine are degraded via the consecutive action of three enzymes to ß-alanine and ß-aminoisobutyric acid, respectively. The third enzyme in the pathway is ß-ureidopropionase (UP), and its deficiency leads to *N*-carbamyl-ß-amino aciduria. Urinary analysis in one case showed elevated levels of *N*-carbamyl-ß-alanine and *N*-carbamyl-ß-aminoisobutyric acid. No activity of ß-ureidopropionase could be detected in a liver biopsy. *Clinical manifestations* in one case include muscular hypotonia, dystonic movements, and severe developmental delay. Neuropathology involves both gray and white matter. The human ß-ureidopropionase gene is located on chromosome 22q11.2. Ureidopropionase deficiency leads to pathologic accumulation of 3-UPA in body fluids. 3-UPA acts as endogenous neurotoxin via inhibition of mitochondrial energy metabolism, resulting in the initiation of secondary, energy-dependent excitotoxic mechanisms. There is no known *treatment* for ureidopropionase deficiency.

Pyrimidine 5'-Nucleotidase Deficiency (Uridine Monophosphate Hydrolase Deficiency)

Erythrocyte maturation is accompanied by RNA degradation and the release of mononucleotides. Pyrimidine 5'-nucleotidase is the first degradative enzyme of the pyrimidine salvage cycle and catalyzes the hydrolysis of pyrimidine 5'-nucleotides to the

corresponding nucleosides. Enzyme deficiency results in the accumulation of high levels of pyrimidine nucleotides in erythrocytes. Homozygous patients with pyrimidine 5'-nucleotidase deficiency present with a nonspherocytic hemolytic anemia with basophilic stippling and splenomegaly, increased indirect bilirubin, and hemoglobinuria. Pyrimidine 5'-nucleotidase deficiency is implicated in the anemia of lead poisoning. This is an autosomal recessive disorder involving a gene on chromosome 7. *Diagnosis* requires demonstration of a complete deficiency of the major isoenzyme, uridine monophosphate hydrolase-1. The enzyme defect should be suspected in patients with nonspherocytic hemolytic anemia with basophilic stippling. The anemia is usually moderate, and transfusions are not usually necessary. There is no specific *treatment*. Splenectomy is not an effective treatment.

Pyrimidine 5'-Nucleotidase Superactivity

Pyrimidine 5'-nucleotidase superactivity may lead to a neurodevelopmental disorder. Four unrelated patients with 6- to 10-fold elevation in the activity of fibroblast pyrimidine 5'-nucleotidase demonstrated normal incorporation of purine bases into nucleotides but decreased incorporation of uridine. *Clinical manifestations* include developmental delay, seizures, ataxia, recurrent infections, severe language deficit, hyperactivity, short attention span, and poor social interaction appearing within the first few years of life. Patients have electroencephalographic abnormalities. Metabolic testing is normal except for persistent hypouricosuria. Increased catabolic activity and decreased pyrimidine salvage may cause a deficiency of pyrimidine nucleotides. *Treatment* is with oral uridine to try to reverse increased nucleotide catabolism. Uridine treatment results in improved speech and behavior, decreased seizure activity, and decreased frequency of infections.

Thymidine Phosphorylase Deficiency

Thymidine phosphorylase catalyzes the conversion of thymidine to thymine. This enzyme is also known as “platelet-derived endothelial cell growth factor,” owing to its angiogenic properties, or “gliostatin,” indicating its inhibitory effects on glial cell proliferation. It has been implicated in mitochondrial nucleoside metabolism. Loss of function of thymidine phosphorylase causes *mitochondrial neurogastrointestinal encephalomyopathy* (MNGIE), an autosomal recessive disorder with mitochondrial DNA alterations. The gene encoding thymidine phosphorylase is the MNGIE gene and is mapped to chromosome 22q13.32-qter. *Clinical manifestations of MNGIE* include ptosis, progressive external ophthalmoparesis, gastrointestinal dysmotility, cachexia, peripheral neuropathy, and leukoencephalopathy. Muscle biopsies reveal mitochondrial abnormalities. The *diagnosis* is made by assay of thymidine phosphorylase activity in peripheral leukocytes. Plasma thymidine level is increased more than 20-fold in MNGIE. Increased thymidine may cause mitochondrial nucleotide pool imbalance, resulting in mitochondrial DNA alterations through a mitochondria-specific thymidine salvage pathway. Supportive treatment is indicated.

Chapter 79 - Progeria

W. Ted Brown

Progeria's most striking feature resembles accelerated aging. This rare syndrome, also referred to as the Hutchinson-Gilford syndrome, has a reported incidence of approximately 1:8 million. Affected children do not become sexually mature or reproduce as a result of severe failure to thrive; parent-to-child transmission has not been observed. Although two sets of identical twins have been noted, no examples of recurrence of classic progeria among siblings are documented. Paternal age is significantly increased, but there is no increase in consanguinity or features associated with dominant mutations or autosomal recessive inheritance. Each child with progeria may represent a new sporadic dominant mutation. The molecular basis of such mutations is unknown.

Clinical Manifestations.

Children with progeria usually appear normal in early infancy, but manifestations such as midfacial cyanosis, “sculpted nose,” and “sclerodema” may suggest the existence of the syndrome at birth. Profound growth failure occurs during the 1st yr of life. The characteristic facies, alopecia, loss of subcutaneous fat, abnormal posture, stiffness of joints, and bone and skin changes usually become apparent during the 2nd yr of life (Fig. 79–1). Motor and mental development is normal. The dominant clinical manifestations include short stature; weight distinctly low for height; diminished subcutaneous fat; head disproportionately large for face; micrognathia; prominent scalp veins; generalized alopecia; prominent eyes; delayed and abnormal dentition; pyriform thorax; short, dystrophic clavicles; “horse-riding” stance; wide-based shuffling gait; coxa valga, thin limbs, and prominent, stiff joints; and failure to complete sexual maturation.

Features frequently present are skin that is thin, taut, dry, wrinkled, and brown spotted in various areas; sclerodermatous skin over the lower abdomen, proximal thighs, and buttocks; prominent superficial veins; loss of eyebrows and eyelashes; persistently patent anterior fontanel; sculpted, beaked nasal tip; faint nasolabial cyanosis; thin lips; protruding ears; absence of ear lobules; thin, high-pitched voice; dystrophic nails; and

Figure 79-1 A 4.5-yr-old girl with height age of 1.75 yr and bone age of 4 yr. (From Wilkins L: *Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*, 3rd ed. Springfield, IL, Charles C Thomas, 1965.)

progressive radiolucency of the terminal phalanges and distal clavicles (acro-osteolysis). A *differential diagnosis* includes neonatal progeroid syndrome, Cockayne syndrome, Hallermann-Streiff syndrome, and mandibular-acral dysplasia. Neonatal progeroid (Weidmann-Rautenstrauch) syndrome is an uncommon autosomal recessive disorder that manifests at birth or thereafter with low birthweight, craniofacial anomalies (pseudohydrocephalus, triangular facies, large fontanel), aged look, lack of subcutaneous fat, natal teeth, developmental delay, and death before the end of the 1st year of life.

Laboratory Findings.

Variable degrees of insulin resistance, occasionally insulin-dependent diabetes mellitus, abnormalities of collagen, increased metabolic rate, and inconsistent abnormalities of serum cholesterol and other lipids are found, but there are no demonstrable abnormalities of thyroid, parathyroid, pituitary, or adrenal function. Twenty-four-hour growth hormone levels are normal, but reduced levels of insulin-like growth factor-1 have been noted. Increased levels of hyaluronic acid may occur in the urine of such patients. Variable decrease of DNA repair has also been observed.

Prognosis.

Children with progeria usually have severe atherosclerosis, and death occurs as a result of complications of cardiac or cerebrovascular disease generally between age 5–20 yr, with a median life span of approximately 13 yr. Cataracts and tumors have infrequently been noted, but many changes associated with normal aging in adults, such as presbycusis, presbyopia, arcus senilis, osteoarthritis, senile personality changes, or Alzheimer disease, are not found.

Treatment.

No specific treatment for this condition exists. There is a progeria family support group. A Progeria Registry exists to help with diagnosis and to define more clearly the incidence and molecular basis of the disorder.

Chapter 80 - The Porphyrias

Shigeru Sassa

The porphyrias are inherited and acquired disorders in which the activities of the enzymes of the heme biosynthetic pathway are partially or almost completely deficient. As a result, abnormally elevated levels of porphyrins and/or their precursors are produced, accumulate in tissues, and are excreted in urine and stool. Heme is composed of ferrous iron and protoporphyrin IX (Fig. 80–1) and is an essential molecule for life as the prosthetic group of heme proteins, such as hemoglobin, myoglobin, mitochondrial and microsomal cytochromes, catalase, peroxidases, nitric oxide synthase, and tryptophan pyrrolase. Patients with porphyrias have either cutaneous photosensitivity caused by accumulation of porphyrins in the skin or neurologic disturbances from accumulation of their precursors, or both.

HEME BIOSYNTHETIC PATHWAY

The first step and the last three steps in the heme biosynthetic pathway occur in the mitochondria; the intermediate steps take place in the cytosol (Fig. 80–2). The two major organs that are active in heme synthesis are the liver and the erythroid bone marrow; inherited enzymatic defects in the porphyrias are mainly expressed in these tissues. In erythroid cells, hemoglobin is made in erythroblasts or reticulocytes, which still contain mitochondria; circulating erythrocytes lack the ability to form heme. cDNA and genomic DNA sequences as well as chromosomal assignment have been defined for all heme pathway enzymes (Table 80–1).

Formation of d-Aminolevulinic Acid (ALA).

d-Aminolevulinate synthase (ALAS), the first enzyme of the heme biosynthetic pathway, catalyzes the condensation of glycine and succinyl CoA (see Fig. 80–2 , step 1). The enzyme is localized in the inner membrane of mitochondria and requires pyridoxal 5'-phosphate as a cofactor. ALAS activity is very low and rate limiting for heme

Figure 80-1 Structure of heme.

A = $-CH_2-COOH$; P = $-CH_2-CH_2-COOH$; M = $-CH_3$; V = $-CH{=}CH_2$; • = carbon atom derived from the a-carbon of glycine; * = location of the a-carbon atom from glycine in the pyrrole ring that undergoes reversion; [] = a presumed intermediate. (Modified from Hayashi N: The synthesis of heme and its regulation. *Protein Nucl Acid Enzyme (Tokyo)* 1987;32:797.)

formation. Hepatic ALAS (nonspecific, or ALAS-N) and erythroid ALAS (ALAS-E) are isozymes that are encoded by two distinct nuclear genes: *ALAS1* and *ALAS2*. The gene locus for human *ALAS1* is at chromosome 3p21, and that for *ALAS2* is at the Xp11.21. Inherited deficiency of ALAS-E is associated with X-linked sideroblastic anemia.

Formation of Porphobilinogen (PBG) from ALA.

Two molecules of ALA are converted by a cytosolic enzyme, *d-aminolevulinate dehydratase* (ALAD), to a monopyrrole, PBG, with the removal of two molecules of water (see Fig. 80–2 , step 2). ALAD deficiency porphyria (ADP) is caused by an almost complete lack of enzyme activity (Fig. 80–3). The human *ALAD* gene is localized at chromosome 9q34 and contains two promoter regions that generate housekeeping and erythroid-specific transcripts by alternate splicing, analogous to the expression of the human *PBGD* gene. The novel expression of housekeeping and erythroid-specific transcripts apparently evolved to ensure sufficient heme biosynthesis for the high-level tissue-specific production of hemoglobin.

ALAD requires an intact sulfhydryl group and a zinc atom per subunit for full activity. Lead inhibits ALAD by displacing zinc from the enzyme, the essential metal for enzyme activity, and results in neurologic disturbances, some of which resemble those of ADP. The most potent inhibitor of the enzyme is succinylacetone, a structural analogue of ALA, which is found in

TABLE 80-1 -- Human Enzymes and Genes for Heme Biosynthesis

Enzyme	Gene Symbol	Chromosomal Location	cDNA (bp)	Protein (aa)	Genome	
					Size (kb)	***Organization****

urine and blood of patients with hereditary tyrosinemia who often develop a condition similar to ADP.

Formation of Hydroxymethylbilane (HMB) from PBG.

Porphobilinogen deaminase (PBGD) catalyzes the condensation of four molecules of PBG to yield a linear tetrapyrrole, HMB. In the absence of the subsequent enzyme, uroporphyrinogen III cosynthase (UCS), the bilin is spontaneously cyclized into the first tetrapyrrole, uroporphyrinogen I. In the presence of UCS, uroporphyrinogen III is formed, which has an inverted D-ring pyrrole (see Fig. 80–2 , step 3). The gene locus for human *PBGD* is at chromosome 11q23?11qter. The expression of the erythroid-specific mRNA is exclusive to erythroid cells. Two distinct mRNAs are produced through alternative splicing of two primary transcripts arising from two promoters. The upstream promoter is active in all tissues, whereas the other promoter, located 3?kb downstream, is active only in erythroid cells.

Formation of Uroporphyrinogen III from HMB.

UCS catalyzes the formation of uroporphyrinogen III from HMB. This involves an

intramolecular rearrangement that affects only ring D of the uroporphyrinogen (see Fig. 80–2 , step 4). Homozygous deficiency of UCS is associated with congenital erythropoietic porphyria (CEP) (see Fig. 80–3). A single *UCS* gene is at the narrow chromosomal region 10q25.3?q26.3.

Formation of Coproporphyrinogen from Uroporphyrinogen.

A cytosolic enzyme, *uroporphyrinogen decarboxylase* (UROD), catalyzes the sequential removal of the four carboxylic groups of the carboxymethyl side chains in uroporphyrinogen to yield coproporphyrinogen (see Fig. 80–2 , step 5). The *UROD* gene has been localized to chromosome 1pter?p21. Porphyria cutanea tarda (PCT) is caused by a partial (or heterozygous) deficiency of UROD, whereas hepatoerythropoietic porphyria (HEP) is caused by a homozygous deficiency of the enzyme (see Fig. 80–3). The enzyme functions as a homodimer. The gene locus encoding for *UROD* is on chromosome 1p34.

Formation of Protoporphyrinogen from Coproporphyrinogen.

Coproporphyrinogen oxidase (CPO) is a mitochondrial enzyme that catalyzes the removal of the carboxyl group and two hydrogens from the propionic groups of pyrrole rings A and B of coproporphyrinogen to form vinyl groups at these positions (see Fig. 80–2 , step 6). The *CPO* gene is localized to chromosome 9. Hereditary coproporphyria (HCP) is caused by a partial (or heterozygous) deficiency of CPO (see Fig. 80–3).

Formation of Protoporphyrin from Protoporphyrinogen.

The oxidation of protoporphyrinogen to protoporphyrin is mediated by protoporphyrinogen *oxidase* (PPO), which catalyzes the removal of six hydrogen atoms from the porphyrinogen nucleus (see Fig. 80–2 , step 7). Variegate porphyria (VP) is caused by a partial (or heterozygous) deficiency of PPO (see Fig. 80–3). The human PPO contains noncovalently bound FAD. The *PPO* gene is on chromosome 1q23 or 1q22.

Formation of Heme from Protoporphyrin.

The final step of heme biosynthesis is the insertion of iron into protoporphyrin (see Fig. 80–2 , step 8). This reaction is catalyzed by the enzyme *ferrochelatase* (FeC). Unlike other steps in the heme biosynthetic pathway, this enzyme uses protoporphyrin IX as a substrate, rather than its reduced form. However, the enzyme specifically requires ferrous, not ferric, iron. The *FeC* gene is on chromosome 18q21.3.

An iron-sulfur cluster, a [2Fe-2S], has been identified in the purified human ferrochelatase at the carboxyl terminus. The putative binding site is a 30-residue region that contains four cysteine residues, which is a fingerprint for a [2Fe-2S] binding motif. The Fe-S cluster is thought to be essential for the mammalian enzyme activity.

REGULATION OF HEME SYNTHESIS

Biosynthesis of heme in the liver is controlled largely by the rate of formation of ALAS, that is, ALAS-N. The enzyme activity in normal liver cells is very low, whereas its level increases dramatically when the liver needs to make more heme and in response to various chemical treatments. The synthesis of the enzyme is also regulated in a feedback fashion by heme, the end product of the biosynthetic pathway. At higher heme concentrations than those that repress the synthesis of ALAS-N, heme induces microsomal heme oxygenase, resulting in enhancement of heme catabolism. Thus, heme concentration is maintained by a balance between the synthesis of ALAS-N and heme oxygenase-1, both of which are under the regulatory influence of heme. In contrast, ALAS-E synthesis in erythroid cells is either refractory to heme treatment or stimulated by such treatment.

PATHOPHYSIOLOGIC CONSEQUENCES OF PORPHYRINS AND THEIR PRECURSORS

Photosensitivity.

Free porphyrins occur only in small amounts in normal tissues, but their levels may become markedly elevated in the porphyrias. On illumination at wavelengths of about 400?nm (Soret band) and in the presence of oxygen, porphyrins cause photodynamic damage to tissues, cells, subcellular elements, and biomolecules through the formation of singlet oxygen.

Figure 80-3 Enzymatic defects in the porphyrias. The enzymatic defect in each porphyria is shown by a *broken line*. In patients, the substrate for the defective enzymatic step accumulates in the tissue and is excreted in large excess into urine and/or stool. Porphyrin precursors, for example, ALA and PBG, may also be increased in patients with acute hepatic porphyrias as a result of derepression of ALAS-N activity.

Neurologic Disturbances.

Acute hepatic porphyrias, that is, ADP, AIP, HCP, and VP, are characterized by neurologic disturbances. Most common symptoms are abdominal pain, disturbances in intestinal motility (e.g., diarrhea and constipation), dysesthesia, muscular paralysis, and respiratory failure, which can often be fatal. The exact nature of the neurologic disturbances in the porphyrias remains unclear.

MOLECULAR GENETICS OF THE PORPHYRIAS

Genetic analysis has elucidated the complex nature of molecular defects in the porphyrias and possible consequences of their gene defects on cellular function. It also offers an explanation why hepatic porphyrias do not accompany anemia, or conversely why erythropoietic porphyrias do not exhibit defective drug metabolism,

which largely reflects the function of hepatic cytochrome P450. The following general conclusions can be made by molecular genetic studies of the porphyrias.

1. In every porphyria, the molecular defect of the enzyme is heterogeneous. There is more than one mutation resulting clinically in a single porphyria disease. There are more than 100 mutations found in the *PBGD* gene in patients with AIP. There are few founder effect mutations, whereas a pedigree-specific mutation (private mutation) of the enzyme gene is very common.
2. The nature of molecular defects is also highly heterogeneous, including promoter mutations, splicing mutations, consensus sequence mutations, mutations producing nonfunctional mRNAs, and mutations resulting in unstable proteins, gene deletions, and so on.
3. Even among the dominant form of porphyrias, a homozygous form of the disease can be found in a few patients. The homozygous form appears to be caused by mutations with lesser pathophysiologic effects than those found in the heterozygous form. The homozygous disease is clinically more severe than the heterozygous disease due to the combination of two mutant alleles. A subset of homozygous diseases among commonly autosomal dominant diseases has been observed in AIP, HCP, VP, and EPP.
4. Clinically homozygous mutations can be caused by either a *homoallelic* or a *heteroallelic* mutation. However, heteroallelic mutation (*compound heterozygosity*) for two separate mutations is far more common than homoallelic mutation.

5. Tissue-specific regulation of heme pathway enzymes may likely be the basis for the tissue-specific expression of different porphyrias.
6. In the case of *PBGD*, a mutation affecting the splicing of the first intron results in an abnormal enzyme in nonerythroid cells, whereas the same mutation has no effect on the erythroid-specific *PBGD*, because the transcription of the erythroid *PBGD* mRNA utilizes a second AUG that is located approximately 3?kb downstream of the mutated site. Thus, even in a single form of acute hepatic porphyria, there may be distinct tissue-specific expression of the disease, depending on the type of mutation.
7. Most of the acute hepatic porphyrias, such as AIP, HCP, and VP, require an additional factor(s) for their clinical expression. Such a factor can either be genetic or environmental. Thus, porphyrias are not only inborn errors of metabolism but also diseases in which environmental factors have an immense impact on their gene expression.
8. Some hepatic porphyria–like symptoms can be elicited by environmental chemicals, which strongly inhibit heme pathway enzymes. For example, PCT may be caused by UROD inhibition owing to hexachlorobenzene ingestion in normal individuals.

CLASSIFICATION OF PORPHYRIAS

There are eight enzymes involved in the synthesis of heme and, with the exception of the first enzyme, which is ALAS, an enzymatic defect at each step of heme synthesis is associated with each form of porphyria (see Fig. 80–3 and Table 80–2).

Porphyrias are classified as either hepatic or erythropoietic, depending on the principal site of expression of the specific enzymatic defect (see Table 80–2). They can also be classified as acute hepatic or cutaneous porphyrias. Acute hepatic porphyrias are characterized clinically by acute episodes of neurologic disturbances and biochemically by an overproduction of porphyrin precursors, whereas cutaneous porphyrias are characterized clinically by cutaneous photosensitivity and biochemically by an excessive production of porphyrins (Table 80–3).

ALAD Deficiency Porphyria (ADP).

ADP is an autosomal recessive disorder resulting from a homozygous ALAD deficiency (see Fig. 80–3 and Table 80–2). This is the most rare form of the porphyrias; clinical manifestations have been primarily neuropathic and severity and the age at onset have varied in the four reported cases, including an infant born with the clinical disease. All these cases were unrelated males in Europe.

TABLE 80-2 -- **The Porphyrias and Their Enzymatic Defects**

Enzyme Deficiency	Porphyria	Principal Site of Expression	Mode of Transmission	Remarks
ALAD	ADP	Liver	Recessive	
PBGD	AIP			
	Type I	Liver	Dominant	CRIM (-)
	Type II	Liver	Dominant	Normal erythrocyte PBGD
	Type III	Liver	Dominant	CRIM (+)
UCS	CEP	Bone marrow	Recessive	
UROD	PCT			
	Type I	Liver		Acquired
	Type II	Liver	Dominant	
	Type III	Liver	Dominant	
	HEP	Liver and bone marrow	Recessive	
CPO	HCP	Liver	Dominant	
PPO	VP	Liver	Dominant	
FeC	EPP	Bone marrow	Dominant	

ALAD = d-aminolevulinate dehydratase; ADP = ALAD deficiency porphyria; PBGD = porphobilinogen deaminase; AIP = acute intermittent porphyria; CRIM = cross-reactive immunologic material; UCS = uroporphyrinogen III cosynthase; CEP = congenital erythropoietic porphyria; UROD = uroporphyrinogen decarboxylase; PCT = porphyria cutanea tarda; HEP = hepatoerythropoietic porphyria; CPO = coproporphyrinogen oxidase; HCP = hereditary coproporphyria; PPO = protoporphyrinogen oxidase; VP = variegate porphyria; FeC = ferrochelatase; EPP = erythropoietic protoporphyria.

From Sassa S, Kappas A: The porphyrias. In Nathan DG, Oski FA (editors): Hematology in Infancy and Childhood, 4th ed. Philadelphia, WB Saunders, 1993, pp 451–71.

CLINICAL MANIFESTATIONS.

Patients with ADP have vomiting, pain in the arms and legs, and neuropathy, which are exacerbated after stress, alcohol use, or decreased food intake. A rare infant with ADP has been reported who has a clinical course from birth onward that includes general muscle hypotonia and respiratory insufficiency.

LABORATORY FINDINGS.

Urinary ALA excretion is markedly elevated, whereas urinary PBG excretion is within the normal range. Urinary and erythrocyte porphyrins are also markedly elevated (100-fold); no satisfactory explanation has yet been advanced to account for this observation. Fecal porphyrin excretion is normal or marginally elevated. Patients with ADP display markedly decreased activities of ALAD in erythrocytes, as well as in nonerythroid cells (2% of normal), and their parents show approximately 50% decreases in enzyme activities.

MOLECULAR PATHOLOGY.

One or both alleles probably produce enzyme proteins with decreased activity. The disease is genetically highly heterogeneous, in that nine distinct point mutations in the *ALAD* gene were found in four patients and in an asymptomatic heterozygous carrier. Patients homozygous for the *ALAD* defect are all heteroallelic, having two distinct *ALAD* mutations in each allele.

DIAGNOSIS.

Definitive diagnosis depends on the demonstration of impaired ALAD activity and deficiency of enzyme protein in erythrocytes. Supporting evidence includes massive elevations in urinary ALA, substantial elevations of porphyrins in urine and erythrocytes, and perhaps modest elevations in fecal porphyrins. Clinical symptoms of ADP occur only in homozygous patients, whereas heterozygous subjects (parents and certain siblings) of the proband remain clinically unaffected. Because multiple causes of ALAD deficiency have been described, all cases considered to have ADP should be confirmed by molecular studies.

TREATMENT.

The similarities in symptoms between ADP and AIP suggest that prudent management of ADP should probably be directed along the same lines as the management of AIP.

Acute Intermittent Porphyria (AIP).

AIP, also termed Swedish porphyria, pyrroloporphyria, or intermittent acute porphyria, is an autosomal dominant disorder resulting from a partial PBGD deficiency (see Fig. 80–3 and Table 80–2). The deficient enzyme activity (~50% of normal) is found in all tissues, including erythrocytes, in the majority of patients (~85%). This is consistent with the heterozygous state of affected individuals. However,

TABLE 80-3 -- **Clinical and Laboratory Features of the Porphyrias**

Porphyria	Clinical Features	Laboratory Features			
		Erythrocytes	***Plasma***	***Urine***	***Stool***
ADP	Neurologic (as in AIP)	ZnPP		ALA	
AIP	Neurologic: nausea, vomiting, abdominal pain, diarrhea, constipation, ileus, dysuria, muscle hypotonia, respiratory failure, sensory neuropathy, seizures			ALA, PBG	
CEP	Photosensitivity: bullae, crusts, scar formation, sclerodermoid change, hyper- and hypopigmentation, hypertrichosis, erythrodontia, hemolytic anemia, splenomegaly	Uro, I, Copro I	Uro I, Copro I	Uro I, Copro I	

PCT	Photosensitivity: skin fragility, bullae, crusts, scar formation, sclerodermoid change, hyper- and hypopigmentation, hypertrichosis	Uro I, 7-carboxyl III	Uro I, 7-carboxyl III Isocopro	Uro, 7-carboxyl,	
HEP	Photosensitivity (as in CEP)	ZnPP	Uro I, 7-carboxyl III	Uro I, 7-carboxyl III	Uro, 7-carboxyl, Isocopro
HCP	Neurologic (as in ADP, AIP, and VP) and photosensitive (as in VP)		Copro	Copro, ALA, PBG	Copro
VP	Neurologic (as in ADP, AIP, and HCP) and photosensitive (as in HCP)		Proto	ALA, PBG	Proto
EPP	Photosensitivity: burning sensation, edema, erythema, itching, scarring vesicles	Proto	Proto		Proto

ADP = ALAD deficiency porphyria; AIP = acute intermittent porphyria; ALA = d-aminolevulinic acid; PBG = porphobilinogen; CEP = congenital erythropoietic porphyria; Uro I = uroporphyrinogen I; PCT = porphyria cutanea tarda; HEP = hepatoerythropoietic porphyria; HCP = hereditary coproporphyria; VP = variegate porphyria; EPP = erythropoietic protoporphyria; Proto = protoporphyrinogen. 7-Carboxyl-7-carboxylporphyrin; Copro-coproporphyrin; Isocoproisocoproporphyrin; Uro-uroporphyrin; ZnPP-zinc protoporphyrin.

From Sassa S, Kappas A:The porphyrias. In Nathan DG, Oski FA (editors): Hematology in Infancy and Childhood, 4th ed. Philadelphia, WB Saunders, 1993, pp 451–71.

a subset of patients (~15%) show deficient enzyme activity only in nonerythroid cells. The majority (~90%) of individuals with PBGD deficiency remain biochemically and clinically normal. Clinical expression of the disease is usually linked to environmental or acquired factors, for example, nutritional status, drugs, corticosteroids, and other chemicals of endogenous or exogenous origin. The cardinal pathobiology of the disease is a neurologic dysfunction that may affect the peripheral, autonomic, or central nervous systems (see Table 80–3).

EPIDEMIOLOGY.

AIP is probably the most common genetic porphyria. The highest incidence occurs in Lapland, Scandinavia, and the United Kingdom, although it has been reported in many population groups. The prevalence of AIP was estimated to be 1–2 in 100,000 in Europe and 2.4 in 100,000 in Finland. The frequency of low PBGD activity, which includes both patients with AIP and latent gene carriers, is as high as 1 in 500 in the general population of Finland. The disorder is expressed clinically after puberty and is more common in women than in men.

CLINICAL MANIFESTATIONS.

Abdominal pain, which may be generalized or localized, is the most common symptom and is often the initial sign of an acute attack. Other gastroenterologic features may include nausea, vomiting, constipation or diarrhea, abdominal distention, and ileus. Urinary retention, incontinence, and dysuria may frequently be observed. In severe cases, the urine develops a port-wine color, owing to a high content of porphobilin, an auto-oxidation product of PBG. Tachycardia and hypertension, and, less frequently, fever, sweating, restlessness, and tremor, are also observed. In up to 40% of patients, hypertension may become sustained between acute attacks.

Neuropathy is a common feature of AIP. Muscle weakness often begins proximally in the legs but may involve the arms or the distal extremities. Motor neuropathy may also involve the cranial nerves or lead to bulbar paralysis, respiratory deficiency, and death. Sensory patchy neuropathy may also occur. Seizures, especially in patients with hyponatremia due to vomiting, inappropriate fluid therapy, or the syndrome of inappropriate antidiuretic hormone secretion, may accompany acute attacks of AIP. The course of an acute attack of AIP is highly variable, both in individuals and among patients, with attacks lasting from a few days to several months. There are no cutaneous manifestations associated with this enzyme deficiency.

Asymptomatic heterozygotes (~90% of subjects with documented PBGD deficiency) may display neither abnormalities in concentrations of porphyrin precursors nor clinical symptoms. Individuals with both latent and previously clinically expressed AIP may be, however, precipitated into an acute attack by endogenous or exogenous environmental factors. There are at least five different classes of *precipitating factors* in this disease:

1. *ALAS-N inducers:* most precipitating factors can be related to an associated increase in the activity of ALAS-N in the liver. An overproduction of ALA then makes the partially deficient PBGD activity rate limiting.
2. *Endocrine factors:* the clinical disease is more common in women, especially at the time of menses. The disease also hardly becomes manifest before puberty.
3. *Calorie intake:* reduced calorie intake often leads to exacerbations of AIP. Additional calories on a diet may reduce PBG excretion and suppress clinical symptoms.
4. *Drugs and foreign chemicals:* many chemicals, for example, barbiturates, sex steroids, and other foreign chemicals that exacerbate porphyria have the potential to induce cytochrome P450. The resultant enhanced demand for heme synthesis may lead to induction of hepatic ALAS-N.
5. *Stress:* stress is known to upregulate the heme oxygenase gene and leads to exacerbations of AIP. Similarly, other forms of stress, including intercurrent illnesses, infections, alcoholic excess, and surgery, are all known to contribute to the genesis of an acute attack of this disorder.

LABORATORY FINDINGS.

Patients with clinically expressed AIP, as well as a few individuals with latent AIP, excrete variably increased amounts of ALA and PBG in the urine between attacks. In the majority of cases, the onset of an acute attack is accompanied by further increases in excretion of these precursors. Acute attacks may also be associated with elevations in the serum concentrations of ALA, PBG, and porphyrins, which are

normally undetectable. Stool porphyrins are usually normal or only slightly elevated in this disorder. The Watson-Schwartz test is widely used as a screening test for urinary PBG. While this test is highly sensitive, it is neither specific nor quantitative, and its results need to be confirmed and quantified by the column chromatographic. Hemoglobin and bilirubin production are normal.

MOLECULAR PATHOLOGY.

Patients with AIP can be classified into three subsets (see Table 80–2). Patients with *type I* mutations are characterized by cross-reactive immunologic material (CRIM)-negative *PBGD* mutation; they exhibit both intermediately reduced enzyme activity and protein content (about 50% of normal). *Type II* mutations are observed in less than 15% of all AIP and are characterized by a decreased PBGD activity in nonerythroid cells, but with normal erythroid PBGD activity. Patients with *type III* mutations are characterized by CRIM-positive mutations, that is, decreased enzyme activity with the presence of structurally abnormal enzyme protein. Various mutations of the human *PBGD* gene have been described in patients with AIP and are summarized in Table 80–3 . Mutations found in type I AIP are single base substitutions or deletions that result in a single amino acid change or in truncated proteins. The mutations found in type II AIP are single base substitutions that occur in the exon/intron boundary of exon 1, resulting in a splicing defect that affects only the nonspecific form of *PBGD*, but not the erythroid-specific *PBGD*, because the transcription of the gene in erythroid cells starts downstream of the site of mutation. Mutations characterizing type III AIP are observed in the region that is thought to be essential for catalytic activity.

There is marked heterogeneity of the molecular defects in AIP. More than 170 mutations of the *PBGD* gene have been reported in this disorder. The molecular heterogeneity of CRIM-negative forms seems to be more extensive than that of CRIM-positive forms. Most mutations in exons 10 and 12 occur at amino acids in the active site, and several of these are known to be involved in binding the primer, or substrate. The CRIM-positive phenotype of these mutations could be detrimental for activity, but they do not necessarily affect the structure of the enzyme.

DIAGNOSIS.

Diagnosis of type I and III AIP can be made by demonstrating decreased PBGD activity in erythrocytes in the majority of patients (about 85%), whereas the distinction between carrier or latent status and clinically expressed AIP requires demonstration of elevated urinary excretion of PBG and ALA. Elevated levels of both ALA and PBG may also be seen in HCP and VP; measurement of urinary and stool porphyrins will usually differentiate these conditions from AIP. The diagnosis of type II AIP requires either the demonstration of PBGD deficiency in nonerythroid cells or DNA hybridization using allele-specific oligonucleotide specific for the mutation.

TREATMENT.

The treatment of AIP as well as that of ADP, HCP, and VP is essentially identical. Treatment between attacks consists of adequate nutritional intake, avoidance of drugs known to exacerbate porphyria, and prompt treatment of other intercurrent diseases or infections. Unresponsive severe cases should be treated with intravenous administration of the carbohydrate dextrose to provide a minimum of 300?g of carbohydrate/24?hr. Intravenous hematin (4?mg/kg, q12h) is also effective in reducing ALA and PBG excretion as well as in curtailing acute attacks. Nasal or subcutaneous administration of long-acting agonistic analogues of luteinizing hormone releasing hormone have been shown to inhibit ovulation and greatly reduce the incidence of perimenstrual attacks of AIP in some women with cyclic exacerbations of the disease. Synthetic heme analogues, for example, Sn-mesoporphyrin, which inhibit heme oxygenase activity, have also been shown to diminish the output of ALA, PBG, and/or porphyrins in AIP and VP patients, presumably because of an effective blockade of heme catabolism.

Congenital Erythropoietic Porphyria (CEP).

CEP, also referred to as Günther disease, is an autosomal recessive disorder (see Fig. 80–3 and Table 80–2). The primary abnormality is a decreased activity of UCS activity, which results in accumulation and hyperexcretion of predominantly type I porphyrins (see Table 80–3). Clinically, this enzymatic defect is expressed in utero as brownish amniotic fluid caused by excessive amounts of porphyrins and results in cutaneous photosensitivity, hemolysis, and a decreased life expectancy after birth.

EPIDEMIOLOGY.

Fewer than 200 cases have been reported, and some of these cases may really have had PCT or HEP. There is no clear racial or sexual predominance.

CLINICAL MANIFESTATIONS.

The diagnosis of CEP is suggested at birth by pink to dark brown staining of the diapers in infants, owing to large amounts of porphyrins in urine. Early onset of cutaneous photosensitivity is characteristic and is exacerbated by exposure to sunlight. Subepidermal bullous lesions progress to crusty erosions, which heal with scarring and either hyperpigmentation or, less commonly, hypopigmentation. Hypertrichosis and alopecia are frequent, and erythrodontia (with red fluorescence under ultraviolet light) is virtually pathognomonic of CEP. Patients may display symptoms and signs of hemolytic anemia with splenomegaly and porphyrin-rich gallstones. Bone marrow shows erythroid hyperplasia, which may result in pathologic fractures or vertebral compression-collapse and shortness of stature. Although the onset of symptoms of CEP is most often observed in early infancy, a few patients

may first present the syndrome as adults.

PATHOGENESIS.

The primary site of expression of the enzymatic defect is the bone marrow; fluorescence secondary to porphyrin accumulation is variably distributed but invariably present. Most marrow normoblasts display fluorescence, principally localized in the nuclei of the cells. Massive elevations of systemic porphyrins in CEP are derived from porphyrin-laden erythrocytes, which accounts for the multiple pathologic processes of the integument.

LABORATORY FINDINGS.

Urinary porphyrins are always elevated (20- to 60-fold) above normal levels. Uroporphyrin and coproporphyrin are mostly type I isomers. Occasionally, anemia may be severe and require transfusion.

MOLECULAR PATHOLOGY.

A variety of mutations that cause CEP are known. These include missense and nonsense mutations, large and small deletions and insertions, splicing defects, and intronic branch point mutations. Most patients are heteroallelic for the UCS mutations, and they are from diverse racial and demographic groups.

DIAGNOSIS.

Pink urine and/or the onset of severe cutaneous photosensitivity in infancy (or rarely in adults) suggest the diagnosis of CEP. Demonstration of elevated urinary, fecal, and erythrocyte porphyrins, with elevated type I isomers of uroporphyrin and coproporphyrin, establishes the diagnosis. Demonstration of a deficiency of UCS activity is definitive.

TREATMENT.

The avoidance of sunlight, of trauma to the skin, and of infections is the most important preventive measure in CEP. Topical sunscreens may be of some help, as may oral treatment with ß-carotene. Transfusions with packed erythrocytes transiently decrease hemolysis and its attendant drive to increased erythropoiesis and also decrease porphyrin excretion. Splenectomy has been used fairly frequently and has produced short-term reductions in hemolysis, porphyrin excretion, and skin manifestations, but not all cases respond. Treatment with charcoal in a man with CEP was reported to have lowered porphyrin levels and induced complete clinical remission during therapy.

Porphyria Cutanea Tarda (PCT) and Hepatoerythropoietic Porphyria (HEP).

PCT is caused by a heterozygous deficiency, and HEP results from a homozygous deficiency of UROD, respectively (see Fig. 80–3 and Table 80–2).

PORPHYRIA CUTANEA TARDA.

PCT refers to a heterogeneous group of cutaneous porphyria diseases caused by UROD deficiency, which may be either inherited or, more commonly, acquired. Both forms of the disease display reductions in hepatic UROD activity, but erythrocyte UROD activity may or may not be decreased, depending on their types. *Type I* PCT is an acquired disease that typically presents in adults, with decreased hepatic but not erythrocyte UROD activity. The disease may occur spontaneously but more commonly occurs in conjunction with precipitating environmental factors such as alcohol, estrogen, or drug use, or in association with other disorders. *Type II* PCT is, in contrast, inherited in an autosomal dominant fashion and is associated with decreased UROD activity in all tissues. *Type III* PCT is also inherited, but the defect is confined to the liver and erythrocyte UROD activity and concentrations are normal.

Epidemiology. PCT is probably the most common of all the porphyrias, but its exact incidence is not known. The disease is recognized worldwide and there is no racial predilection except among the Bantus in South Africa, secondary to their high incidence of hemosiderosis. Type I PCT is generally more common than type II PCT in Europe, South Africa, and South America. Previously, PCT was thought to be more common in men than women, perhaps secondary to their higher alcohol intake; the incidence in females has increased to the level seen in males, perhaps owing to increased use of contraceptive steroids, postmenopausal estrogens, and alcohol.

Clinical Manifestations. The pathognomonic clinical feature of PCT is the formation of vesicles on sun-exposed areas of the skin, particularly the dorsa of the hands. Crusting, superficial scar, milia formation, and residual pigmentation supersede the vesicles. Facial hypertrichosis may be present and is conspicuous. Hypopigmented indurated plaques of skin may develop and resemble those seen in scleroderma. Photo-onycholysis is occasionally present. Neurologic dysfunction does not occur in PCT.

Pathogenesis. Phototoxic porphyrins in the skin may be largely derived from the liver or formed locally in the skin. Activation of the complement system after irradiation has been demonstrated in PCT patients and is presumed to result from the generation of reactive oxygen species. Bullous fluid is known to contain prostaglandin E_2 , and photoactivation of uroporphyrin damages lysosomes. Liver from patients with PCT almost invariably displays siderosis with fatty changes, necrosis, chronic inflammatory changes, and granuloma formation. Iron, estrogens, alcohol, and chlorinated hydrocarbons, which are all potential hepatotoxins, may aggravate PCT. Either the homozygous or heterozygous presence of the C282Y and H63D mutations of the hemochromatosis *(HFE)* gene may predispose to the development of PCT. Increased prevalence of the C282Y mutation is increased in both sporadic (type I) and familial (type II) PCT. These associations will be more clearly understood when the function of the *HFE* gene is established and the functional significance of the C282Y and H63D mutations with regard to iron absorption are defined. The incidence of hepatitis B and C infection may also be higher than normal in PCT patients. The incidence of hepatocellular carcinoma in PCT is known to be greater than in the general population. A significant association

of HIV-infected patients with PCT has been reported.

Laboratory Findings. Increased concentrations of uroporphyrin (mainly isomer I) and 7-carboxylic porphyrins (isomer III) are found in the urine in PCT, with lesser increases of coproporphyrin and 5- and 6-carboxylic porphyrins. Small quantities of isocoproporphyrin may be detected in serum or in urine, but in feces this is often the dominant porphyrin excreted and represents the most important diagnostic criterion for PCT. Total daily fecal porphyrin excretion exceeds total urinary porphyrin excretion. Skin porphyrins are increased, especially in areas that are protected from photoactivation. Serum iron and ferritin concentrations are frequently elevated.

Molecular Pathology. More than 10 *UROD* mutations responsible for PCT are known. Familial (type II) PCT is associated with heterozygous UROD deficiency. In contrast, HEP is due to homozygous or compound heterozygous state for mutations of the gene encoding this enzyme. Most *UROD* mutations found in HEP have not been found in familial PCT and are associated with residual UROD activity. The heterozygous *UROD* mutations in most cases of familial PCT appear to be more critical to the enzyme activity than those found in HEP. However, a few families with cases of both HEP and PCT have been described.

Diagnosis. The clinical picture in PCT is fairly specific but can be confused with other photosensitive porphyric (VP) and nonporphyric (systemic lupus erythematosus or scleroderma) diseases. Urinary fluorescence under ultraviolet light illumination, quantification of porphyrins and separation and identification of porphyrins by thin-layer chromatography, and high-performance liquid chromatography will assist the diagnosis. Plasma porphyrins are elevated in PCT and in other photosensitizing porphyrias. Fecal porphyrin levels are often elevated; isocoproporphyrin, or an isocoproporphyrin:coproporphyrin ratio of 0.1 or higher, is virtually diagnostic of PCT.

Treatment. In type I PCT, the identification and avoidance of precipitating factors is the first line of treatment. The clinical response to cessation of alcohol ingestion is highly variable; nonetheless, abstinence should be recommended because of the association with a history of heavy alcohol ingestion. Phlebotomy is usually effective in reducing urinary porphyrin concentrations and in induction of clinical remissions. There is strong evidence that the beneficial effects of phlebotomy result from a diminution in the stores of body iron. If phlebotomy is ineffective or contraindicated owing to the presence of other diseases such as anemia, low-dose chloroquine therapy may be considered. Efficacy of chloroquine therapy and phlebotomy is probably similar, and a combined approach may diminish the incidence of side effects. The mechanism of chloroquine therapy may be related to its ability to chelate porphyrins in a water-soluble and, hence, more easily excretable form.

HEPATOERYTHROPOIETIC PORPHYRIA.

HEP is a rare form of porphyria probably resulting from a homozygous defect of UROD. Clinically, HEP is characterized by the childhood onset of severe photosensitivity and skin fragility and is indistinguishable from CEP. Some 20 cases are known.

Clinical Manifestations. These findings are very similar to those seen in CEP. Pink urine, severe photosensitivity leading to scarring and mutilation of sun-exposed areas of skin, sclerodermoid changes, hypertrichosis, erythrodontia, anemia (often hemolytic), and hepatosplenomegaly characterize HEP. Onset is usually in early infancy or childhood, but adult onset has also been described. In contrast to PCT, serum iron concentrations are usually normal and phlebotomy has no beneficial effects in HEP patients.

Laboratory Findings. Elevations in urinary porphyrins, predominantly uroporphyrin of isomer type I with lesser quantities of 7-carboxylic porphyrins, mainly type III, are commonly found. Isocoproporphyrin concentrations equal to or greater than coproporphyrin are also found in urine and feces. Elevated erythrocyte Zn-protoporphyrin is commonly observed (see Table 80–3). Anemia and biochemical evidence of impaired hepatic function is highly variable.

Molecular Pathology. In contrast to familial (type II) PCT, which is associated with heterozygous UROD deficiency, HEP is the result of a homozygous, or compound heterozygous, state for mutations of the gene. Although HEP is associated with marked UROD deficiency, there is some residual UROD activity. With a few exceptions, *UROD* mutations found in HEP are unique and not found in familial PCT. *UROD* mutations found in HEP appear to be less severe individually, but in the homozygous or compound heterozygous state they are associated with

severe enzyme deficiencies. HEP is genetically heterogeneous. Both CRIM-positive and CRIM-negative mutations have been described.

DIAGNOSIS.

The diagnosis must be suspected in patients with severe photosensitivity and especially considered in the differential diagnosis of CEP. Diagnostic criteria include elevated levels of fecal or urinary isocoproporphyrin and erythrocyte Zn-protoporphyrin. Differential diagnosis of HEP includes EPP in which erythrocyte protoporphyrin is also elevated but in which, in contrast to HEP, urinary porphyrins are normal. EPP is also clinically milder than HEP. Measurement of erythrocyte or fibroblast UROD activities typically shows reductions to 2–10% of normal control values with intermediate reductions of UROD activities in family members.

TREATMENT.

Avoidance of the sun and the use of topical sunscreens is essentially all that can be offered to these patients. A response to phlebotomy has not been observed, although this is perhaps not surprising because serum iron levels, in contrast to those in PCT patients, are invariably normal.

Hereditary Coproporphyria (HCP).

HCP is a disease caused by a heterozygous deficiency of CPO activity, which is inherited in an autosomal dominant manner (see Fig. 80–3 and Table 80–2). Clinically, the disease is similar to ADP or AIP, although it is often milder;

additionally, HCP may be associated with photosensitivity. Expression of the disease is variable and influenced by similar precipitating factors responsible for the exacerbation of AIP. Very rarely, homozygous deficiency of this enzyme may occur and is associated with a more severe form of the disease.

EPIDEMIOLOGY.

Clinically expressed HCP is much less common than is clinically expressed AIP, but, as with the latter disease, latent HCP or HCP gene carriers are found with greater frequency.

CLINICAL MANIFESTATIONS.

Neurovisceral symptomatology is essentially indistinguishable from that of ADP or AIP. Abdominal pain, vomiting, constipation, neuropathies, and psychiatric manifestations are common. Cutaneous photosensitivity is a feature in about 30% of cases. Pregnancy, the menstrual cycle, and contraceptive steroids can precipitate attacks, but the most common precipitating factor is drug administration, most notably phenobarbital.

LABORATORY FINDINGS.

The biochemical hallmark of HCP is hyperexcretion of coproporphyrin (predominantly type III) into the urine and feces. Fecal coproporphyrin may be chelated with copper, and fecal protoporphyrin may be modestly elevated. Hyperexcretion of ALA, PBG, and uroporphyrin into the urine may accompany exacerbations of the disease, but, in contrast to AIP, these findings generally normalize between attacks. CPO activity is typically reduced by about 50% in heterozygotes and by about 90–98% in homozygotes.

MOLECULAR PATHOLOGY.

The first disease-specific mutation of the CPO gene reported was a C?T transition at position 691, resulting in an Arg?Trp substitution in the protein, in a patient with homozygous HCP. This substitution results in the synthesis of an unstable protein with a residual activity. A G265?A transition, involving the highly conserved glycine residue at the 89th position, was detected in a patient with heterozygous HCP. A transition A?G mutation at position 910 of the coding sequence of the CPO mRNA was found in a variant homozygous form of HCP, *harderoporphyria*; this mutation led to the substitution of a lysine residue by glutamic acid (K304E). Several other mutations in the *CPO* gene are known, but all mutations including two for the homoallelic form of HCP and harderoporphyria, are different.

DIAGNOSIS.

The diagnosis of HCP should be suspected in patients with the signs, symptoms, and clinical course characteristic of the acute hepatic porphyrias (ADP, AIP, HCP, and VP) but in whom PBGD activity is normal. Urinary excretion of heme precursors is similar in HCP and VP, but the predominant or exclusive presence of fecal coproporphyrin is highly suggestive of HCP. Fecal or urinary predominance of harderoporphyrin, with greatly reduced CPO activity, was reported in a case of harderoporphyria, a variant form of HCP.

TREATMENT.

The identification and avoidance of precipitating factors is essential. Treatment of acute attacks is similar to the treatment of AIP.

Variegate Porphyria (VP).

VP, also termed *porphyria variegata*, protocoproporphyria, South African genetic porphyria, or Royal malady, is caused by a heterozygous deficiency in PPO activity and is inherited in an autosomal dominant manner (see Fig. 80–3 and Table 80–2). Patients with this disorder may show neurovisceral symptoms, photosensitivity, or both (Table 80–3). Very rare forms of VP are seen with homozygous deficiencies in PPO activity.

EPIDEMIOLOGY.

The incidence of VP of 3 in 1,000 in South Africa is substantially higher than elsewhere. The disease is recognized worldwide, and, with the exception of South Africa, there is no racial or geographic predilection. Outside of South Africa, VP is probably less common than AIP.

CLINICAL MANIFESTATIONS.

The neurovisceral symptomatology is identical to that observed in ADP, AIP, and HCP. Photosensitivity is more common, and the resulting lesions tend to be more chronic in VP than in HCP. Cutaneous manifestations comprise vesicles, bullae, hyperpigmentation, milia, hypertrichosis, and increased skin fragility. Lesions are clinically and histologically indistinguishable from PCT. Skin manifestations are less frequently observed in cold climates than in hot climates. The same spectrum of factors that leads to activation of ADP, AIP, and HCP may also exacerbate VP. Barbiturates, dapsone, lead from “moonshine” whiskey, contraceptive steroids, pregnancy, and decreased carbohydrate intake all induce or exacerbate VP.

PATHOGENESIS.

PPO activity in most patients with VP is decreased more than 50%. In rare cases of homozygous VP, however, there is a virtual absence of PPO activity. Symptoms include severe photosensitivity, growth and mental retardation, and marked neurologic abnormalities in some cases; onset of homozygous VP starts in childhood.

LABORATORY FINDINGS.

The biochemical hallmark of VP is elevated fecal porphyrin, usually with protoporphyrin IX exceeding coproporphyrin (mostly isomer III). Fecal X-porphyrins (ether-acetic acid-insoluble, extracted with urea-Triton), a heterogeneous group of

porphyrin-peptide conjugates, are elevated in VP more than in any other type of porphyria. Urinary coproporphyrin (type III), ALA, and PBG are often normal between attacks but may become markedly elevated during acute attacks. Plasma invariably shows a fluorescence emission that probably represents a protoporphyrin-peptide conjugate.

MOLECULAR PATHOLOGY.

Various disease-specific PPO mutations have been reported in families with VP from around the world. One of the mutations (R59W) represents the founder gene underlying the high incidence of VP in South Africa. Rare homozygotes for VP have been shown to be mostly *heteroallelic* for defects in the *PPO* gene, with the exception of one who was *homoallelic*.

DIAGNOSIS.

VP should be considered in the differential diagnosis of acute porphyria, especially if PBGD activity is normal. Characteristic plasma porphyrin fluorescence, having a different fluorescence emission maximum from PCT, is seen in VP. The differentiation of VP from HCP is usually possible after fecal porphyrin analysis and in patients with only cutaneous manifestations. The demonstration of urinary 8- and 7-carboxylic porphyrins and isocoproporphyrin in PCT is usually sufficient for differentiation from VP. PPO deficiency can be demonstrated in fibroblasts or lymphocytes.

TREATMENT.

Identification and avoidance of precipitating factors is essential. Protective clothing can minimize photosensitivity,

---

and canthaxanthin (a ß-carotene analogue) may be of some help. The treatment of neurovisceral symptoms is identical to that described for AIP.

Erythropoietic Protoporphyria (EPP).

EPP, also referred to as protoporphyria, or erythrohepatic protoporphyria, is associated with a partial deficiency of FeC and is inherited in an autosomal dominant fashion (see Fig. 80–3 and Table 80–2). Biochemically, this defect results in massive accumulations of protoporphyrin in erythrocytes, plasma, and feces. The disease is characterized by the childhood onset of cutaneous photosensitivity in light-exposed areas, but skin lesions are milder and less disfiguring than those seen in CEP.

EPIDEMIOLOGY.

EPP is the most common form of erythropoietic porphyria. There is no racial or sexual predilection, and onset is typically in childhood.

CLINICAL MANIFESTATIONS.

Cutaneous photosensitivity of EPP is quite different from that seen in CEP or PCT. Stinging or painful burning sensations in the skin occur within 1?hr of exposure to the sun and are followed several hours later by erythema and edema. Some patients experience burning sensations in the absence of such objective signs of cutaneous phototoxicity that result in the erroneous diagnosis of a psychiatric illness. Petechiae, or more rarely, purpura, vesicles, and crusting, may develop and persist for several days after sun exposure. Artificial lights may also cause photosensitivity, especially operating theater lights. Symptoms are usually worse during spring and summer and occur in light-exposed areas, especially on the face and hands. Intense and repeated exposure to the sun may result in onycholysis, leathery hyperkeratotic skin over the dorsa of the hands, and mild scarring. Gallstones, sometimes presenting at an unusually early age, are fairly common, and hepatic disease, although unusual, may be severe and associated with significant morbidity. Anemia is uncommon. There are no known precipitating factors and no neurovisceral manifestations.

PATHOGENESIS.

The peak light absorption range for porphyrins corresponds well to the wavelength of light (circa 400?nm) known to trigger photosensitivity reactions in the skin of EPP patients. Light-excited porphyrins generate free radicals and singlet oxygen that may lead to peroxidation of lipids and cross-linking of membrane proteins, which, in erythrocytes, may result in reduced deformability and thus hemolysis. Interestingly, protoporphyrin, but not Zn-protoporphyrin, is released from erythrocytes after irradiation, which may explain why EPP is associated with photosensitivity whereas lead intoxication and iron deficiency are not. Forearm irradiation in EPP patients leads to complement activation and polymorphonuclear chemotaxis. Similar results have been obtained in vitro, and these events may also contribute to the pathogenesis of skin lesions in EPP.

LABORATORY FINDINGS.

The biochemical hallmark of EPP is excessive concentrations of free protoporphyrin in erythrocytes, plasma, bile, and feces; this is due to its poor solubility in water, not in urine. The bone marrow and the newly released erythrocytes appear to be the major source of elevated protoporphyrin concentrations, although the liver may contribute in certain cases.

MOLECULAR PATHOLOGY.

Molecular analysis of ferrochelatase mutations reveals missense mutations, splicing abnormalities, intragenic deletions, and possible nonsense mutations associated with functional deficiency of ferrochelatase. Exon skipping is the most predominant. Incomplete penetrance and variable clinical expression remain as puzzling features of EPP. There is no strict correlation between the genetic defects and the erythrocyte protoporphyrin levels or between the abnormal ferrochelatase activity and EPP

disease severity.

DIAGNOSIS.

Photosensitivity, which is quite distinct from that seen in CEP or PCT, should suggest the diagnosis, which can be confirmed by the demonstration of elevated concentrations of free protoporphyrin in erythrocytes, plasma, and stools with normal urinary porphyrins. The presence of protoporphyrin in both plasma and erythrocytes is specific for EPP. Fluorescent reticulocytes on examination of a peripheral blood smear may also suggest the diagnosis.

TREATMENT.

Avoidance of the sun and use of topical sunscreen agents may be helpful. Oral administration of ß-carotene may afford systemic photoprotection, resulting in improved, though highly variable, tolerance to the sun. The recommended serum ß-carotene level of 600–800?µg/dL is usually achieved with oral doses of 120–180?mg daily, and beneficial effects are typically seen 1–3 mo after the onset of therapy. The mechanism probably involves quenching of activated oxygen radicals.

Chapter 81 - Hypoglycemia

Mark A. Sperling

Glucose has a central role in fuel economy and is a source of energy storage in the form of glycogen, fat, and protein (see Chapter 76). Glucose, an immediate source of energy, provides 38?mol of adenosine triphosphate (ATP)/mol of glucose oxidized. It is important for cerebral energy metabolism because it is usually the preferred substrate and its utilization accounts for nearly all the oxygen consumption in brain. Cerebral glucose uptake occurs through a glucose transporter molecule or molecules that are not regulated by insulin. Cerebral transport of glucose is a carrier-mediated, facilitated diffusion process that is dependent on blood glucose concentration. Deficiency of brain glucose transporters can result in seizures because of low cerebral glucose concentrations despite normal blood glucose levels. To maintain the blood glucose concentration and prevent it from precipitously falling to levels that impair brain function, an elaborate regulatory system has evolved.

The defense against hypoglycemia is integrated by the autonomic nervous system and by hormones that act in concert to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis while simultaneously limiting peripheral glucose utilization. Hypoglycemia represents a defect in one or several of the complex interactions that normally integrate glucose homeostasis during feeding and fasting. This process is particularly important for neonates, in whom there is an abrupt transition from intrauterine life, characterized by dependence on transplacental glucose supply, to extrauterine life, characterized ultimately by the autonomous ability to maintain euglycemia. Because prematurity or placental insufficiency may limit tissue nutrient deposits, and genetic abnormalities in enzymes or hormones may become evident in the neonate, hypoglycemia is common in the neonatal period.

Definition.

In neonates, there is not always an obvious correlation between blood glucose concentration and the classic clinical manifestations of hypoglycemia. The absence of symptoms does not indicate that glucose concentration is normal and has not fallen to less than some optimal level for maintaining brain metabolism. There is evidence that hypoxemia and ischemia may potentiate the role of hypoglycemia in causing permanent brain damage. Consequently, the lower limit of accepted normality of the blood glucose level in newborn infants with associated illness that already impairs cerebral metabolism has not been determined (see Chapter 96). Out of concern for possible neurologic, intellectual, or psychologic sequelae in later life, many authorities now urge that any value of blood glucose less than 50?mg/dL in neonates be viewed with suspicion and vigorously treated. This is particularly applicable after the initial 2–3?hr of life, when glucose normally has reached its nadir; subsequently, blood glucose levels begin to rise and achieve values of 50vmg/dL or higher after 12–24?hr. In older infants and children, a whole blood glucose concentration of less than 50?mg/dL (10–15% higher for serum or plasma) represents hypoglycemia.

Significance and Sequelae.

Metabolism by the adult brain accounts for the majority of total basal glucose turnover. Most of the endogenous hepatic glucose production in infants and young children can be accounted for by brain metabolism. Furthermore, there is a correlation between glucose production and estimated brain weight at all ages.

Because the brain grows most rapidly during the 1st yr of life and because the larger proportion of glucose turnover is used for brain metabolism, sustained or repetitive hypoglycemia in infants and children can retard brain development and function. In the rapidly growing brain, glucose may also be a source of membrane lipids and protein synthesis; structural proteins and myelination are important for normal brain maturation. Under conditions of severe and sustained hypoglycemia, these cerebral structural substrates may have to be degraded to energy-usable intermediates such as lactate, pyruvate, amino acids, and ketoacids, which can support brain metabolism at the expense of brain growth. The capacity of the newborn brain to take up and oxidize ketone bodies is about fivefold greater than that of the adult brain. However, the capacity of the liver to produce ketone bodies may be limited in the newborn period, especially in the presence of hyperinsulinemia, which acutely inhibits hepatic glucose output, lipolysis, and ketogenesis, thereby depriving the brain of alternate fuel sources. The deprivation of the brain's major energy source during hypoglycemia and the limited availability of alternate fuel sources during hyperinsulinemia have predictable adverse consequences on brain metabolism and growth: decreased brain oxygen consumption and increased breakdown of endogenous structural components with destruction of functional membrane integrity. Hypoglycemia may thus lead to permanent impairment of brain growth and function. The potentiating effects of hypoxia may exacerbate brain damage or indeed be responsible for it when blood glucose values are not in the classic hypoglycemic range.

The major long-term sequelae of severe, prolonged hypoglycemia are mental retardation or recurrent seizure activity, or both. Subtle effects on personality are also possible but have not been clearly defined. Permanent neurologic sequelae are present in more than half of patients with severe recurrent hypoglycemia who are younger than 6 mo of age, the period of most rapid brain growth. These sequelae may be reflected in pathologic changes characterized by atrophic gyri, reduced myelination in cerebral white matter, and atrophy in the cerebral cortex. Infarcts are absent if hypoxia-ischemia did not contribute to cerebral manifestations, and the cerebellum is spared if hypoglycemia is the sole insult. These sequelae are more

likely when alternative fuel sources are limited as occurs with hyperinsulinemia, when the episodes of hypoglycemia are repetitive or prolonged, or when they are compounded by hypoxia. There is no precise knowledge relating the duration or severity of hypoglycemia to subsequent neurologic development of children in a predictable manner. Although less common, hypoglycemia in older children may also produce long-term neurologic defects through neuronal death mediated, in part, by cerebral excitotoxins released during hypoglycemia.

Substrate, Enzyme, and Hormonal Integration of Glucose Homeostasis

IN THE NEWBORN (see also Chapter 96).

Under nonstressed conditions, fetal glucose is derived entirely from the mother through placental transfer. Therefore, fetal glucose concentration usually reflects but is slightly lower than maternal glucose levels. Catecholamine release, which occurs with fetal stress such as hypoxia, mobilizes fetal glucose and free fatty acids (FFAs) through ß-adrenergic mechanisms, reflecting ß-adrenergic activity in fetal liver and adipose tissue. Catecholamines may also inhibit fetal insulin and stimulate glucagon release.

The acute interruption of maternal glucose transfer to the fetus at delivery imposes an immediate need to mobilize endogenous glucose. Three related events facilitate this transition: changes in hormones, changes in their receptors, and changes in key enzyme activity. There is a three- to fivefold abrupt increase in glucagon concentration within minutes to hours of birth. The level of insulin usually falls initially and remains in the basal range for several days without demonstrating the usual brisk response to physiologic stimuli such as glucose. A dramatic surge in spontaneous catecholamine secretion is also characteristic. Epinephrine can also augment growth hormone secretion by a-adrenergic mechanisms; growth hormone levels are elevated at birth. Acting in unison, these hormonal

changes at birth mobilize glucose via glycogenolysis and gluconeogenesis, activate lipolysis, and promote ketogenesis. As a result of these processes, plasma glucose concentration stabilizes after a transient decrease immediately after birth, liver glycogen stores become rapidly depleted within hours of birth, and gluconeogenesis from alanine, a major gluconeogenic amino acid, can account for approximately 10% of glucose turnover in the human newborn infant by several hours of age. FFA concentrations also increase sharply in concert with the surges in glucagon and epinephrine and are followed by rises in ketone bodies. Glucose is thus spared for brain utilization while FFAs and ketones provide alternative fuel sources for muscle as well as essential gluconeogenic factors such as acetyl-coenzyme A (CoA) and the reduced form of nicotinamide-adenine dinucleotide (NADH) from hepatic fatty acid oxidation, which is required to drive gluconeogenesis.

In the early postnatal period, responses of the endocrine pancreas favor glucagon secretion so that blood glucose concentration can be maintained. These adaptive changes in hormone secretion are paralleled by similarly striking adaptive changes in hormone receptors. Key enzymes involved in glucose production also change dramatically in the perinatal period. Thus, there is a rapid fall in glycogen synthase activity and a sharp rise in phosphorylase after delivery. Similarly, the amount of rate-limiting enzyme for gluconeogenesis, phosphoenol-pyruvate carboxykinase, rises dramatically after birth, activated in part by the surge in glucagon and the fall in insulin. This framework can explain several causes of neonatal hypoglycemia based on inappropriate changes in hormone secretion and unavailability of adequate reserves of substrates in the form of hepatic glycogen, muscle as a source of amino acids for gluconeogenesis, and lipid stores for the release of fatty acids. In addition, appropriate activities of key enzymes governing glucose homeostasis are required (see Fig. 76–1 (Figure Not Available)).

IN OLDER INFANTS AND CHILDREN.

Hypoglycemia in older infants and children is analogous to that of adults, in whom glucose homeostasis is maintained by glycogenolysis in the immediate postfeeding period and by gluconeogenesis several hours after meals. The liver of a 10-kg child contains 20–25?g of glycogen, which is sufficient to meet normal glucose requirements of 4–6?mg/kg/min for only 6–12?hr. Beyond this period, hepatic gluconeogenesis must be activated. Both glycogenolysis and gluconeogenesis depend on the metabolic pathway summarized in Figure 76–1 (Figure Not Available) . Defects in gluconeogenesis may not be manifested in infants until the frequent feeding of 3- to 4-hr intervals ceases and infants sleep through the night, a situation usually present by 3–6 mo of age. The source of gluconeogenic precursors is derived primarily from muscle protein. The muscle bulk of infants and small children is substantially smaller relative to body mass than that of adults, whereas glucose requirements/unit of body mass are greater in children, so the ability to compensate for glucose deprivation by gluconeogenesis is more limited in infants and young children, as is the ability to withstand fasting for prolonged periods. The ability of muscle to generate alanine, the principal gluconeogenic amino acid, may also be limited. Thus, in normal young children, the blood glucose level falls after 24?hr of fasting, insulin concentrations fall appropriately to levels of less than 5–10?µU/mL, lipolysis and ketogenesis are activated, and ketones may appear in the urine.

The switch from glycogen synthesis during and immediately after meals to glycogen breakdown and later gluconeogenesis is governed by hormones, of which insulin is of central importance. Plasma insulin concentrations increase to peak levels of 50–100?µU/mL after meals, which serve to lower the blood glucose concentration through the activation of glycogen synthesis, enhancement of peripheral glucose uptake, and inhibition of glucose production. In addition, lipogenesis is stimulated whereas lipolysis and ketogenesis are curtailed. During fasting, plasma insulin concentrations fall to 5–10?µU/mL or less, and, together with other hormonal changes, this fall results in activation of gluconeogenic pathways (see Fig. 76–1 (Figure Not Available)). Fasting glucose concentrations are maintained through the activation of glycogenolysis and gluconeogenesis, inhibition of glycogen synthesis, and activation of lipolysis and ketogenesis. It should be emphasized that a plasma insulin concentration of greater than 5?µU/mL, in association with a blood glucose concentration of 40?mg/dL (2.2?mM) or less, is abnormal, indicating a hyperinsulinemic state and failure of the mechanisms that normally result in suppression of insulin secretion during fasting or hypoglycemia.

The hypoglycemic effects of insulin are opposed by the actions of several hormones whose concentration in plasma increases as blood glucose falls. These

counterregulatory hormones, glucagon, growth hormone, cortisol, and epinephrine, act in concert by increasing blood glucose concentrations via activating glycogenolytic enzymes (glucagon, epinephrine); inducing gluconeogenic enzymes (glucagon, cortisol); inhibiting glucose uptake by muscle (epinephrine, growth hormone, cortisol); mobilizing amino acids from muscle for gluconeogenesis (cortisol); activating lipolysis; providing glycerol for gluconeogenesis and fatty acids for ketogenesis (epinephrine, cortisol, growth hormone, glucagon); and inhibiting insulin release and promotion of growth hormone and glucagon secretion (epinephrine).

Congenital or acquired deficiencies in these hormones may rarely result in hypoglycemia, which occurs when endogenous glucose production cannot be mobilized to meet energy needs in the postabsorptive state, that is, 8–12?hr after meals or during fasting. Concurrent deficiency of several hormones (hypopituitarism) may result in hypoglycemia that is more severe or appears earlier during fasting than that seen with isolated hormone deficiencies. For practical purposes the majority of the causes of hypoglycemia in infancy and childhood reflect inappropriate adaptation to fasting.

Clinical Manifestations (see also Chapter 96).

Clinical features generally fall into two categories. The first includes symptoms associated with the activation of the autonomic nervous system and epinephrine release, usually seen with a rapid decline in blood glucose concentration (Box 81–1). The second category includes symptoms due to decreased cerebral glucose utilization, usually associated with a slow decline in blood glucose level or prolonged hypoglycemia (see Box 81–1). Although these classic symptoms occur in older children, the symptoms of hypoglycemia in infants may be subtler and include cyanosis, apnea, hypothermia, hypotonia, poor feeding, lethargy, and seizures. Some of these symptoms may be so mild that they are missed. Occasionally, hypoglycemia may be asymptomatic in the immediate newborn period. Newborns with hyperinsulinemia are often large for gestational age; older infants with hyperinsulinemia may eat excessively because of chronic hypoglycemia and become obese. In childhood, hypoglycemia may present as behavior problems, inattention, ravenous appetite, or seizures. It may be misdiagnosed as epilepsy, inebriation, personality disorders, hysteria, and retardation. A blood glucose determination should always be performed in sick neonates, who should be vigorously treated if concentrations are less than 50?mg/dL. At any age level, hypoglycemia should be considered a cause of an initial episode of convulsions or a sudden deterioration in psychobehavioral functioning.

Classification of Hypoglycemia in Infants and Children.

Classification is based on knowledge of the control of glucose homeostasis in infants and children (Box 81–2).

NEONATAL, TRANSIENT, SMALL FOR GESTATIONAL AGE, AND PREMATURE INFANTS (see Chapter 96).

The overall incidence of symptomatic hypoglycemia in newborns is 1–3 per 1,000 live births. This incidence is increased severalfold in certain high-risk neonatal groups (see Box 81–2). The premature

†Common.

and small for gestational age (SGA) infants are vulnerable to the development of hypoglycemia. The factors responsible for the high frequency of hypoglycemia in this group, as well as in other groups outlined in Box 81–2 , are related to the inadequate stores of liver glycogen, muscle protein, and body fat needed to sustain the substrates required to meet energy needs. These infants are small by virtue of prematurity or impaired placental transfer of nutrients. Their enzyme systems for gluconeogenesis may not be fully developed.

In contrast to deficiency of substrates or enzymes, the hormonal system appears to be functioning normally at birth in most low-risk neonates. Despite hypoglycemia, plasma concentrations of alanine, lactate, and pyruvate are higher, implying their diminished rate of utilization as substrates for gluconeogenesis. Infusion of alanine elicits further glucagon secretion but causes no significant rise in glucose. During the initial 24?hr of life, plasma concentrations of acetoacetate and ß-hydroxybutyrate are lower in SGA infants than in full-term infants, implying diminished lipid stores, diminished fatty acid mobilization, or impaired ketogenesis, or a combination of these conditions. Diminished lipid stores are most likely because fat (triglyceride) feeding of newborns results in a rise in the plasma levels of glucose, FFAs, and ketones. In addition, infants with perinatal asphyxia and some SGA newborns may have transient hyperinsulinemia, which promotes hypoglycemia and diminishes FFAs.

The role of FFAs and their oxidation in stimulating neonatal gluconeogenesis is essential. The provision of FFAs as triglyceride feedings from formula or human milk together with gluconeogenic precursors may prevent the hypoglycemia that usually ensues after neonatal fasting. For these and other reasons, milk feedings are introduced early (at birth or within 4–6?hr) after delivery. In the hospital setting, when feeding is precluded by virtue of respiratory distress or when feedings alone cannot maintain blood glucose concentrations at levels greater than 50?mg/dL, intravenous glucose at a rate that supplies 4–8?mg/kg/min should be started. Infants with transient neonatal hypoglycemia can usually maintain the blood glucose level spontaneously after 2–3 days of life.

INFANTS BORN TO DIABETIC MOTHERS (see Chapter 96).

Of the transient hyperinsulinemic states, infants born to diabetic mothers are the most common. Gestational diabetes affects some 2% of pregnant women, and approximately 1/1,000 pregnant women have insulin-dependent diabetes. At birth, infants born to these mothers may be large and plethoric, and their body stores of glycogen, protein, and fat are replete.

Hypoglycemia in infants of diabetic mothers is mostly related to hyperinsulinemia and partly related to diminished glucagon secretion. Hypertrophy and hyperplasia of the islets is present, as is a brisk, biphasic, and typically mature insulin response to glucose; this insulin response is absent in normal infants. Infants born to diabetic mothers also have a subnormal surge in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli and, initially, excessive sympathetic activity that may lead to adrenomedullary exhaustion as reflected by decreased urinary excretion of epinephrine. The normal plasma hormonal pattern of low insulin, high glucagon, and high catecholamines is reversed to a pattern of high insulin, low glucagon, and low epinephrine. As a consequence of this abnormal hormonal profile, the endogenous glucose production is significantly inhibited compared with that in normal infants, thus predisposing them to hypoglycemia.

Infants born with *erythroblastosis fetalis* also may have hyperinsulinemia and share many physical features, such as large body size, with infants born to diabetic mothers. The cause of the hyperinsulinemia in infants with erythroblastosis is not entirely clear.

Mothers whose diabetes has been well controlled during pregnancy, labor, and delivery generally have infants near normal size who are less likely to acquire neonatal hypoglycemia and other complications formerly considered typical of such infants (see Chapter 96). In supplying glucose to hypoglycemic infants, it is important to avoid hyperglycemia that evokes a prompt exuberant insulin release, which may result in rebound hypoglycemia. When needed, glucose should be provided at continuous infusion rates of 4–8?mg/kg/min, but the appropriate dose for each patient should be individually adjusted. During labor and delivery, maternal hyperglycemia should be avoided because it results in fetal hyperglycemia, which predisposes to hypoglycemia when the glucose supply is interrupted at birth. Hypoglycemia persisting or occurring after 1 wk of life requires an evaluation for the causes listed in Box 81–2 .

HYPERINSULINISM.

Most children with hyperinsulinism that causes hypoglycemia present in the neonatal period or in infancy; hyperinsulinism is the most common cause of persistent hypoglycemia in early infancy. Hyperinsulinemic infants may be macrosomic at birth, reflecting the anabolic effects of insulin in utero. There is, however, no history and no biochemical evidence of maternal diabetes. The onset is from birth to 18 mo of age, but occasionally it is first evident in older children. Insulin concentrations are inappropriately elevated at the time of documented hypoglycemia; with non-hyperinsulinemic hypoglycemia, plasma insulin concentrations should be less than 5?µU/mL and no higher than 10?µU/mL. In affected infants, however, plasma insulin concentrations at the time of hypoglycemia are commonly greater than 5–10?µU/mL. Some authorities set more stringent criteria, arguing that any value of insulin higher than 2?µU/mL with hypoglycemia is abnormal. The insulin (µU/mL):glucose (mg/dL) ratio is commonly 0.4 or greater; plasma ketones and FFA levels are low. Macrosomic infants may present with hypoglycemia from the first days of life. Infants with lesser degrees of hyperinsulinemia, however, may manifest hypoglycemia after the first few weeks to months, when the frequency of feedings has been decreased to permit

the infant to sleep through the night and hyperinsulinemia prevents the mobilization of endogenous glucose. Increasing appetite and demands for feeding, wilting spells, jitteriness, and frank seizures are the most common presenting features. Additional clues include the rapid development of fasting hypoglycemia within 4–8?hr of food deprivation compared with other causes of hypoglycemia (Tables 81–1 and 81–2); the need for high rates of exogenous glucose infusion to prevent hypoglycemia, often at rates greater than 10–15?mg/kg/min; absence of ketonemia or acidosis; and elevated C-peptide or proinsulin levels at the time of hypoglycemia. The latter insulin-related products are absent in factitious hypoglycemia from exogenous administration of insulin. Provocative tests with tolbutamide or leucine are not necessary in infants; hypoglycemia is invariably provoked by withholding feedings for several hours, permitting simultaneous measurement of glucose, insulin, ketones, and FFAs in the same sample at the time of clinically manifested hypoglycemia. The glycemic response to glucagon at the time of hypoglycemia reveals a brisk rise in glucose of at least 40?mg/dL and implies that glucose mobilization has been restrained by insulin but that glycogenolytic mechanisms are intact (Boxes 81–3 , 81–4 , and 81–5).

The measurement of serum insulin-like growth factor binding protein-1 (IGFBP-1) concentration may help diagnose hyperinsulinemia. The secretion of IGFBP-1 is acutely inhibited by insulin; IGFBP-1 concentrations are low during hyperinsulinism-induced hypoglycemia. In patients with spontaneous or fasting-induced hypoglycemia with a low insulin level (ketotic hypoglycemia, normal fasting), IGFBP-1 concentrations are significantly higher.

The differential diagnosis of endogenous hyperinsulinism includes *familial and nonfamilial hyperinsulinism of infancy due to diffuse* ß*-cell hyperplasia*, or focal ß-cell hyperplasia or adenomas. The plasma levels of insulin alone cannot distinguish these entities. They represent a variety of genetic defects responsible for abnormalities in the endocrine pancreas that is characterized by

Rise in glucose of = 40?mg/dL after glucagon given at the time of hypoglycemia strongly suggests a hyperinsulinemic state with adequate hepatic glycogen stores and intact glycogenolytic enzymes. If ammonia is elevated to 100–200?µM, consider activating mutation of glutamate dehydrogenase.

autonomous insulin secretion and that is not appropriately reduced when blood glucose declines spontaneously or in response to provocative maneuvers such as fasting (see Box 81–5 and Table 81–3). Clinical, biochemical, and molecular genetic approaches now permit classification of congenital hyperinsulinism, formerly termed nesidioblastosis, into distinct entities. One form of persistent hyperinsulinemic hypoglycemia of infancy (PHHI) is inherited in an autosomal recessive pattern, is severe, and is caused by mutations in the regulation of the potassium channel intimately involved in insulin secretion by the pancreatic b cell (Fig. 81–1). Normally, glucose entry into the b cell is enabled by the non–insulin-responsive glucose transporter GLUT-2. On entry, glucose is phosphorylated to glucose-6-phosphate by the enzyme glucokinase, enabling glucose

Box 81-4. Criteria for Diagnosing Hyperinsulinism Based on "Critical" Samples (Drawn at a Time of Fasting Hypoglycemia: Plasma Glucose <50?mg/dL)

1. Hyperinsulinemia (plasma insulin > 2?µU/mL)*
2. Hypofattyacidemia (plasma free fatty acids < 1.5?mmol/L)
3. Hypoketonemia (plasma ß-hydroxybutyrate: < 2.0?mmol/L)
4. Inappropriate glycemic response to glucagon, 1?mg IV (delta glucose > 40?mg/dL)

Box 81-5. Diagnosis of Acute Hypoglycemia in Infants and Children

ACUTE SYMPTOMS PRESENT

1. Obtain blood sample before and 30?min after glucagon administration.
2. Obtain urine as soon as possible. Examine for ketones; if not present and hypoglycemia confirmed, suspect hyperinsulinemia or fatty acid oxidation defect; if present, suspect ketotic, hormone deficiency, inborn error of glycogen metabolism, or defective gluconeogenesis.
3. Measure glucose in the original blood sample. If hypoglycemia is confirmed, proceed with substrate-hormone measurement as in Box 81–3 .
4. If glycemic increment after glucagon exceeds 40?mg/dL above basal, suspect hyperinsulinemia.
5. If insulin level at time of confirmed hypoglycemia is greater than 5?µU/mL, suspect endogenous hyperinsulinemia; if greater than 100?µU/mL, suspect factitious hyperinsulinemia (exogenous insulin injection). Admit to hospital for supervised fast.
6. If cortisol is less than 10?µg/dL or growth hormone is less than 5?ng/mL, or both, suspect adrenal insufficiency or pituitary disease, or both. Admit to hospital for hormonal testing and neuroimaging.

HISTORY SUGGESTIVE: ACUTE SYMPTOMS NOT PRESENT

1. Careful history for relation of symptoms to time and type of food intake, bearing in mind age of patient. Exclude possibility of

1. Careful history for relation of symptoms to time and type of food intake, bearing in mind age of patient. Exclude possibility of alcohol or drug ingestion. Assess possibility of insulin injection, salt craving, growth velocity, intracranial pathology.
2. Careful examination for hepatomegaly (glycogen storage disease; defect in gluconeogenesis); pigmentation (adrenal failure); stature and neurologic status (pituitary disease)
3. Admit to hospital for provocative testing:
   a. 24-hr fast under careful observation; when symptoms provoked proceed with steps 1–4 as when acute symptoms present
   b. Pituitary-adrenal function using arginine-insulin stimulation test if indicated
4. Liver biopsy for histologic and enzyme determinations if indicated
5. Oral glucose tolerance test (1.75?g/kg; max 75?g) if reactive hypoglycemia suspected (dumping syndrome, etc.)

metabolism to generate ATP. The rise in the molar ratio of ATP relative to adenosine diphosphate (ADP) closes the ATP-sensitive potassium channel in the cell membrane (KATPchannel). This channel is composed of two subunits, the KIR6.2 channel, part of the family of inward-rectifier potassium channels, and a regulatory component in intimate association with KIR6.2 known as the sulfonylurea receptor (SUR). Together, KIR6.2 and SUR constitute the potassium-sensitive ATP channel KATP. Normally, the KATP is open, but with the rise in ATP and closure of the channel, potassium accumulates intracellularly, causing depolarization of the membrane, opening of voltage-gated calcium channels, influx of calcium into the cytoplasm, and secretion of insulin via exocytosis. The genes for both SUR and KIR6.2 are located close together on the short arm of chromosome 11, the site of the insulin gene. Inactivating mutations in the gene for SUR, or, less often, KIR6.2, prevent the potassium channel from opening; it remains essentially closed with constant depolarization and, therefore, constant inward flux

Figure 81-1 Schematic representation of the pancreatic cell with some important steps in insulin secretion. The membrane-spanning, adenosine triphosphate (ATP)-sensitive potassium (K^+) channel (K_{ATP}) consists of two subunits: the sulfonylurea receptor (SUR) and the inward rectifying K channel (K_{IR} 6.2). In the resting state, the ratio of ATP to adenosine diphosphate (ADP) maintains K_{ATP} in an open state, permitting efflux of intracellular K^+. When blood glucose concentration rises, its entry into the ß cell is facilitated by the GLUT-2 glucose transporter, a process not regulated by insulin. Within the ß cell, glucose is converted to glucose-6-phosphate by the enzyme glucokinase and then undergoes metabolism to generate energy. The resultant increase in ATP relative to ADP closes K_{ATP}, preventing efflux of K^+, and the rise of intracellular K^+ depolarizes the cell membrane and opens a calcium (Ca^{2+}) channel. The intracellular rise in Ca^{2+} triggers insulin secretion via exocytosis. Sulfonylureas trigger insulin secretion by reacting with their receptor (SUR) to close K_{ATP}; diazoxide inhibits this process, whereas somatostatin, or its analogue octreotide, inhibits insulin secretion by interfering with calcium influx. Genetic mutations in SUR or K_{IR} 6.2 that prevent K_{ATP} from being open are responsible for autosomal recessive forms of persistent hyperinsulinemic hypoglycemia of infancy (PHHI). One form of autosomal dominant PHHI is due to an activating mutation in glucokinase. The amino acid leucine also triggers insulin secretion by closure of K_{ATP}. Metabolism of leucine is facilitated by the enzyme glutamate dehydrogenase (GDH), and overactivity of this enzyme in the pancreas leads to hyperinsulinemia with hypoglycemia, associated with hyperammonemia from overactivity of GDH in the liver. X = inhibition; 4 = stimulation.

of calcium; hence, insulin secretion is continuous. A milder autosomal dominant form of these defects has also been reported. Likewise, an activating mutation in glucokinase results in closure of the potassium channel through overproduction of ATP and hyperinsulinism. Inactivating mutations of the glucokinase gene are responsible for inadequate insulin secretion and form the basis of type 2 maturity-onset diabetes of youth (see Chapter 583).

The familial forms of PHHI are more common in certain populations, notably Arabic and Ashkenazi Jewish communities, where it may reach an incidence of about 1/2,500, compared with the sporadic rates in the general population of approximately 1/50,000. These *autosomal recessive forms* of PHHI typically present in the immediate newborn period as macrosomic newborns with a weight in excess of 4.0?kg and severe recurrent or persistent hypoglycemia manifesting in the initial hours or days of life. Glucose infusions as high as 15–20?mg/kg/min and frequent feedings fail to maintain euglycemia. Diazoxide, which could function by opening K_{ATP} channels (see Fig. 81–1), fails to control hypoglycemia adequately. Somatostatin, which also opens K_{ATP} and inhibits calcium flux, may be partially effective in about 50% of patients (see Fig. 81–1). Calcium channel blocking agents may have an effect. When affected patients are unresponsive to these measures, pancreatectomy is strongly recommended to avoid the long-term neurologic sequelae of hypoglycemia. If surgery is undertaken, preoperative CT or MRI rarely reveals an isolated adenoma, permitting local resection. Also, intraoperative ultrasonography may identify a small impalpable adenoma, permitting local resection. Adenomas often present in late infancy or early childhood. Distinguishing between focal and diffuse cases of persistent hyperinsulinism with the use of a combination of transhepatic portal venous catheterization and selective pancreatic venous blood sampling to measure insulin levels as well as intraoperative histologic techniques are possibly helpful. Diffuse hyperinsulinism is characterized by large ß cells with abnormally large nuclei, whereas focal adenomatous lesions display small and normal ß cell nuclei. Although *SUR1* mutations are present in both types, the focal lesions arise by a random loss of a maternally imprinted growth-inhibitory gene on maternal chromosome 11p in association with paternal transmission of a mutated *SUR1* or K_{IR} 6.2 paternal chromosome 11p. Local excision of focal adenomatous islet-cell hyperplasia results in a cure with little or no recurrence. If local resection is not possible, near-total resection of 85–90% of the pancreas is recommended. In contrast, the near-total pancreatectomy required for the diffuse hyperplastic lesions is often associated with persistent hypoglycemia and later development of hyperglycemia or frank, insulin-requiring diabetes mellitus.

Further resection of the remaining pancreas may occasionally be necessary if

hypoglycemia recurs and cannot be controlled by medical measures, such as the use of somatostatin or diazoxide.

Experienced pediatric surgeons in medical centers equipped to provide the necessary preoperative and postoperative care, diagnostic evaluation, and management should perform surgery. In some patients who have been managed medically, hyperinsulinemia and hypoglycemia regress over months. This is similar to what occurs in children with the hyperinsulinemic hypoglycemia seen in Beckwith-Wiedemann syndrome.

If hypoglycemia first manifests between 3 and 6 mo of age or later, a therapeutic trial using medical approaches with somatostatin, diazoxide, and frequent feedings can be attempted for up to 2–4 wk. Failure to maintain euglycemia without undesirable side effects from the drugs may prompt the need for surgery. Some success in suppressing insulin release and correcting hypoglycemia in patients with PHHI has been reported with the use of the long-acting somatostatin analogue octreotide. Most cases of neonatal PHHI are sporadic; familial forms permit genetic counseling on the basis of anticipated autosomal recessive inheritance. However, infants manifesting hypoglycemia at 3–6 mo of age are likely to have other forms of PHHI.

A second form of familial PHHI suggests *autosomal dominant inheritance*. The clinical features tend to be less severe, and onset of hypoglycemia is most likely, but not exclusively, to occur beyond the immediate newborn period and usually beyond the period of weaning at an average age at onset of about 1 yr. At birth, macrosomia is rarely observed, and response to diazoxide is almost uniform. The initial presentation may be delayed and occur as late as 30 yr, unless provoked by fasting. The genetic basis for this autosomal dominant form has not been delineated; it is not always linked to K_{IR} 6.2/SUR, and the activating mutation in glucokinase is transmitted in an autosomal dominant manner. If a family history is present, genetic counseling for a 50% recurrence rate can be given for future offspring.

A third form of persistent PHHI is associated with *mild hyperammonemia*, usually as a sporadic occurrence although dominant inheritance occurs. Presentation is more like the autosomal dominant form rather than the autosomal recessive form. Diet and diazoxide control symptoms, but pancreatectomy may be necessary in some cases. The association of hyperinsulinism and hyperammonemia is caused by an inherited or de novo gain-of-function mutation in the enzyme glutamate dehydrogenase. The resulting increase in glutamate oxidation in the pancreatic ß cell raises the ATP concentration and, hence, the ratio of ATP:ADP, which closes K_{ATP} , leading to membrane depolarization, calcium influx, and insulin secretion (see Fig. 81–1). In the liver, the excessive oxidation of glutamate to ß-ketoglutarate may generate ammonia and divert glutamate from being processed to *N*-acetylglutamate, an essential cofactor for removal of ammonia through the urea cycle via activation of the enzyme carbamoyl phosphate synthetase. The hyperammonemia is mild, with concentrations of 100–200?µM/L, and produces no central nervous system (CNS) symptoms or consequences as seen in other hyperammonemic states. Leucine, a potent amino acid for stimulating insulin secretion and implicated in leucine-sensitive hypoglycemia, acts by allosterically stimulating glutamate dehydrogenase. Thus, *leucine-sensitive hypoglycemia* may be a form of the hyperinsulinemia-hyperammonemia syndrome or a potentiation of mild disorders of the K_{ATP} channel.

Hypoglycemia associated with hyperinsulinemia is also seen in approximately 50% of patients with the *Beckwith-Wiedemann syndrome* (see Chapter 96). This syndrome is characterized by exomphalos, gigantism, macroglossia, microcephaly, and visceromegaly. Distinctive lateral earlobe fissures are present, and hemihypertrophy occurs in many of these infants. Diffuse islet cell hyperplasia occurs in infants with hypoglycemia. The diagnostic and therapeutic approaches are the same as those discussed previously, although microcephaly and retarded brain development may occur independently of hypoglycemia. Patients with the Beckwith-Wiedemann syndrome may acquire tumors, including Wilms' tumor, hepatoblastoma, adrenal carcinoma, and rhabdomyosarcoma. This overgrowth syndrome is caused by mutations in the chromosome 11p15.5 region close to the genes for insulin, SUR, K_{IR} 6.2, and IGF-2. Duplications in this region and genetic imprinting from a defective or absent copy of the maternally derived gene are involved in the variable features and patterns of transmission. Hypoglycemia may resolve over weeks to months of medical therapy. Pancreatic resection may also be needed.

Hyperinsulinemic hypoglycemia in infancy is reported as a manifestation of one form of congenital disorder of glycosylation. Disorders of protein glycosylation usually present with neurologic symptoms but also may include liver dysfunction with hepatomegaly, intractable diarrhea, protein-losing enteropathy, and hypoglycemia (see Chapter 76.6). These disorders are often underdiagnosed. One entity associated with hyperinsulinemic hypoglycemia is caused by phosphomannose isomerase deficiency, and clinical improvement followed supplemental treatment with oral mannose at a dose of 0.17?g/kg six times per day.

After the first 12 mo of life, hyperinsulinemic states are uncommon until islet cell adenomas reappear, as a cause after the patient is several years of age. Hyperinsulinemia due to *islet cell adenoma* should be considered in any child 5 yr or older presenting with hypoglycemia. The diagnostic approach is outlined in Table 81–3 and Box 81–5 . Fasting for 24–36?hr usually provokes hypoglycemia; coexisting hyperinsulinemia confirms the diagnosis provided that factitious administration of insulin by the parents, a form of *Munchausen syndrome by proxy*, is excluded. Occasionally, provocative tests may be required. Exogenously administered insulin can be distinguished from endogenous insulin by simultaneous measurement of C-peptide concentration. If C-peptide levels are elevated, endogenous insulin secretion is responsible for the hypoglycemia; if C-peptide levels are low but insulin values are high, exogenous insulin has been administered, perhaps as a form of child abuse. Islet cell adenomas at this age are treated by surgical excision; familial multiple endocrine adenomatosis type I (Wermer syndrome) should be considered in the differential diagnosis. Antibodies to insulin or the insulin receptor (insulin mimetic action) are also rarely associated with hypoglycemia. Some tumors produce insulin-like growth factors, thereby provoking hypoglycemia by interacting with the insulin receptor.

A rare form of hyperinsulinemic hypoglycemia has been reported after exercise. Whereas glucose and insulin remain unchanged in most people after moderate, short-term exercise, rare patients manifest severe hypoglycemia with

hyperinsulinemia 15–50?min after the same standardized exercise. This form of exercise-induced hyperinsulinism is believed to be caused by an abnormal responsiveness of ß-cell insulin release in response to pyruvate generated during exercise.

ENDOCRINE DEFICIENCY.

Hypoglycemia associated with endocrine deficiency is usually caused by adrenal insufficiency with or without associated growth hormone deficiency (see Chapters 551 and 569). In panhypopituitarism, isolated adrenocorticotropic hormone (ACTH) or growth hormone deficiency, or combined ACTH deficiency plus growth hormone deficiency, the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism; in males, a microphallus may provide a clue to a coexistent deficiency of gonadotropin. Newborns with hypopituitarism often have a form of “hepatitis” and the syndrome of *septo-optic dysplasia*. When adrenal disease is severe, as in congenital adrenal hyperplasia caused by cortisol synthetic enzyme defects, adrenal hemorrhage, or congenital absence of the adrenal glands, disturbances in serum electrolytes with hyponatremia and hyperkalemia or ambiguous genitals may provide diagnostic clues (see Chapter 570). In older children,

0 = absence; ? *or* ? *indicates respectively small increase or decrease;* ?? *or* ?? *indicates respectiv text.*

failure of growth should suggest growth hormone deficiency. Hyperpigmentation may provide the clue to Addison disease with increased ACTH levels or adrenal unresponsiveness to ACTH owing to a defect in the adrenal receptor for ACTH. The frequent association of Addison disease in childhood with hypoparathyroidism (hypocalcemia), chronic mucocutaneous candidiasis, and other endocrinopathies should be considered. Adrenoleukodystrophy should also be considered in the differential diagnosis of primary Addison disease in older children (see Chapter 75.2).

Hypoglycemia in cortisol-growth hormone deficiency may be caused by decreased gluconeogenic enzymes with cortisol deficiency, increased glucose utilization due to a lack of the antagonistic effects of growth hormone on insulin action, or failure to supply endogenous gluconeogenic substrate in the form of alanine and lactate with compensatory breakdown of fat and generation of ketones. Deficiency of these hormones results in reduced gluconeogenic substrate, which resembles the syndrome of ketotic hypoglycemia. Investigation of a child with hypoglycemia, therefore, requires exclusion of ACTH-cortisol or growth hormone deficiency and, if diagnosed, its appropriate replacement with cortisol or growth hormone.

Epinephrine deficiency could theoretically be responsible for hypoglycemia. Urinary excretion of epinephrine has been diminished in some patients with spontaneous or insulin-induced hypoglycemia in whom absence of pallor and tachycardia was also noted, suggesting that failure of catecholamine release, due to a defect anywhere along the hypothalamic-autonomic-adrenomedullary axis, might be responsible for the hypoglycemia. This possibility has been challenged, owing to the rarity of hypoglycemia in patients with bilateral adrenalectomy, provided that they receive adequate glucocorticoid replacement and because diminished epinephrine excretion is found in normal patients with repeated insulin-induced hypoglycemia. Many of the

patients described as having hypoglycemia with failure of epinephrine excretion fit the criteria for ketotic hypoglycemia.

Glucagon deficiency in infants or children may rarely be associated with hypoglycemia.

SUBSTRATE LIMITED

Ketotic Hypoglycemia. This is the most common form of childhood hypoglycemia. This condition usually presents between the ages of 18 mo and 5 yr and remits spontaneously by the age of 8–9 yr. Hypoglycemic episodes typically occur during periods of intercurrent illness when food intake is limited. The classic history is of a child who eats poorly or completely avoids the evening meal, is difficult to arouse from sleep the following morning, and may have a seizure or be comatose by midmorning. Another common presentation occurs when parents sleep late and the affected child is unable to eat breakfast, thus prolonging the overnight fast.

At the time of documented hypoglycemia, there is associated ketonuria and ketonemia; plasma insulin concentrations are appropriately low, 5–10?µU/mL or less, thus excluding hyperinsulinemia. A ketogenic provocative diet, formerly used as a diagnostic test, is not essential to establish the diagnosis because fasting alone provokes a hypoglycemic episode with ketonemia and ketonuria within 12–18?hr in susceptible individuals. Normal children of similar age can withstand fasting without hypoglycemia developing during the same period, although even normal children may acquire these features by 36?hr of fasting.

Children with ketotic hypoglycemia have plasma alanine concentrations that are markedly reduced in the basal state after an overnight fast and decline even further with prolonged fasting. Alanine, produced in muscle, is a major gluconeogenic precursor. Alanine is the only amino acid that is significantly lower in these children, and infusions of alanine (250?mg/kg) produce a rapid rise in plasma glucose without causing significant changes in blood lactate or pyruvate levels, indicating that the entire gluconeogenic pathway from the level of pyruvate is intact but that there is a deficiency of substrate. Glycogenolytic pathways are also intact because glucagon induces a normal glycemic response in affected children during the fed state. The levels of hormones that counter hypoglycemia are appropriately elevated, and insulin is appropriately low.

The *etiology* of ketotic hypoglycemia may be a defect in any of the complex steps involved in protein catabolism, oxidative deamination of amino acids, transamination, alanine synthesis, or alanine efflux from muscle. Children with ketotic hypoglycemia are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia. Any decrease in muscle mass may compromise the supply of gluconeogenic substrate at a time when glucose demands per unit of body weight are already relatively high, thus predisposing the patient to the rapid development of hypoglycemia, with ketosis representing the attempt to switch to an alternative fuel supply. Children with ketotic hypoglycemia may represent the low end of the spectrum of children's capacity to tolerate fasting. Similar relative intolerance to fasting is present in normal children, who cannot maintain blood glucose after 30–36?hr of fasting, compared with the adult's capacity for prolonged fasting. Although the defect may be present at birth, it may not be evident until the child is stressed by more prolonged periods of calorie restriction. Moreover, the spontaneous remission observed in children at age 8–9 yr might be explained by the increase in muscle bulk with its resultant increase in supply of endogenous substrate and the relative decrease in glucose requirement per unit of body mass with increasing age. There is also some evidence to support the contention that impaired epinephrine secretion from immaturity of autonomic innervation contributes to ketotic hypoglycemia. Rarely, inborn errors of fatty acid metabolism present as ketotic hypoglycemia, although, typically, fatty acid oxidation defects produce hypoketotic hypoglycemia.

In anticipation of spontaneous resolution of this syndrome, *treatment* of ketotic hypoglycemia consists of frequent feedings of a high-protein, high-carbohydrate diet. During intercurrent illnesses, parents should test the child's urine for the presence of ketones, the appearance of which precedes hypoglycemia by several hours. In the presence of ketonuria, liquids of high carbohydrate content should be offered to the child. If these cannot be tolerated, the child should be offered a short course of corticosteroids or admitted to the hospital for intravenous glucose administration.

Branched-Chain Ketonuria (Maple Syrup Urine Disease) (see Chapter 74.6). The hypoglycemic episodes were once attributed to high levels of leucine, but evidence indicates that interference with the production of alanine and its availability as a gluconeogenic substrate during calorie deprivation is responsible for hypoglycemia.

GLYCOGEN STORAGE DISEASE. See Chapter 76.1

Glucose-6-Phosphatase Deficiency (Type I Glycogen Storage Disease). Affected children usually display a remarkable tolerance to their chronic hypoglycemia; blood glucose values in the range of 20–50?mg/dL are not associated with the classic symptoms of hypoglycemia, possibly reflecting the adaptation of the CNS to ketone bodies as an alternative fuel.

Affected untreated children manifest growth failure, mental retardation, and a shortened life span unless they are treated. Continuous intragastric feeding improves the metabolic and clinical findings by reducing the frequency and severity of hypoglycemia, thereby avoiding the secondary hormonal changes that appear to be responsible for the metabolic derangements. Continuous intragastric feeding at night, combined with frequent daytime feedings, produces equally effective amelioration of the biochemical disturbances and avoids the inconvenience of 24-hr continuous gastric feeding. The daytime feedings are given every 3–4?hr: 60–70% of the calories as carbohydrate low in fructose and galactose, 12–15% of the calories as protein, and

15–25% of the calories as fat. At night, a small nasogastric tube is passed by the patient (or a parent for younger children), and approximately one third of the daily caloric requirements is continuously infused over 8–12?hr using a small continuous infusion pump. One commercially available formula for nocturnal infusion contains 89% of the calories as glucose and glucose oligosaccharides, 1.8% as safflower oil, and 9.2% as crystalline amino acids (Vivonex, Eaton Laboratories). Nocturnal cornstarch therapy is also beneficial. Transient nocturnal hypoglycemia is not

completely prevented, and renal glomerular dysfunction plus formation of hepatic adenoma remain serious complications. Liver transplantation offers promise of long-term cure.

Amylo-1,6-Glucosidase Deficiency (Debrancher Enzyme Deficiency; Type III Glycogen Storage Disease). See Chapter 76 .

Liver Phosphorylase Deficiency (Type VI Glycogen Storage Disease) (see also Chapter 76). Low hepatic phosphorylase activity may result from a defect in any of the steps of activation; a variety of defects have been described. Hepatomegaly, excessive deposition of glycogen in liver, growth retardation, and occasional symptomatic hypoglycemia occur. A diet high in protein and reduced in carbohydrate usually prevents hypoglycemia.

Glycogen Synthetase Deficiency (see also Chapter 76). The inability to synthesize glycogen is extremely rare. There is fasting hypoglycemia and hyperketonemia; hyperglycemia with glucosuria occurs after meals. During fasting hypoglycemia, levels of the counterregulatory hormones, including catecholamines, are appropriately elevated or normal, and insulin levels are appropriately low. The liver is not enlarged. Protein-rich feedings at frequent intervals result in dramatic clinical improvement, including growth velocity. This condition mimics the syndrome of ketotic hypoglycemia and should be considered in the differential diagnosis of that syndrome.

DISORDERS OF GLUCONEOGENESIS

Fructose-1,6-Diphosphatase Deficiency (see Chapter 76.3). A deficiency of this enzyme results in a block of gluconeogenesis from all possible precursors below the level of fructose-1,6-diphosphate. Infusion of these gluconeogenic precursors results in lactic acidosis without a rise in glucose; acute hypoglycemia may be provoked by inhibition of glycogenolysis. Glycogenolysis remains intact, and glucagon elicits a normal glycemic response in the fed, but not in the fasted, state. Accordingly, affected individuals have hypoglycemia only during caloric deprivation, as in fasting, or during intercurrent illness. As long as glycogen stores remain normal, hypoglycemia does not develop. In affected families, there may be a history of siblings with known hepatomegaly who died in infancy with unexplained metabolic acidosis.

Clinical features simulate those of type I glycogen storage disease. Hepatomegaly in individuals with fructose-1,6-diphosphatase deficiency is due to lipid storage rather than glycogen storage. Lactic acidosis, ketosis, hyperlipidemia, and hyperuricemia occur; their pathogenesis is related to the severity and duration of hypoglycemia and the resultant low levels of insulin and high levels of counterregulatory hormones. Therapy for these infants, consisting of a diet high in carbohydrates (56%, excluding fructose, which cannot be utilized), low in protein (12%), and normal in fat composition (32%), has permitted normal growth and development. Continuous nocturnal provision of calories through the intragastric infusion system described earlier for type I glycogen storage disease is also applicable to children with fructose-1,6-diphosphatase deficiency. During intercurrent illnesses with vomiting, intravenous glucose infusion is necessary to prevent severe hypoglycemia.

Defects in Fatty Acid Oxidation (see also Chapter 75). The important role of fatty acid oxidation in maintaining gluconeogenesis is underscored by examples of congenital or drug-induced defects in fatty acid metabolism that may be associated with fasting hypoglycemia.

Various congenital enzymatic deficiencies causing defective carnitine or fatty acid metabolism occur. A severe and relatively common form of fasting hypoglycemia with hepatomegaly, cardiomyopathy, and hypotonia occurs with long- and medium-chain fatty acid coenzyme-A dehydrogenase deficiency (LCAD and MCAD). Plasma carnitine levels are low, ketones are not present in urine, but dicarboxylic aciduria is present. Clinically, patients with *acyl CoA dehydrogenase deficiency* present with a Reye-like syndrome, recurrent episodes of severe fasting hypoglycemic coma, and cardiorespiratory arrest (sudden infant death syndrome-like events). Severe hypoglycemia and metabolic acidosis without ketosis also occur in patients with multiple acyl-CoA dehydrogenase disorders. Hypotonia, seizures, and acrid odor are other clinical clues. Survival depends on whether the defects are severe or mild; diagnosis is established from studies of enzyme activity in liver biopsy tissue or in cultured fibroblasts from affected patients. Tandem mass spectrometry can be employed for blood samples, even those on filter paper, for screening of congenital inborn errors. The frequency of this disorder is at least 1/10,000–15,000 births; molecular diagnostic methods are being developed. Avoidance of fasting and supplementation with carnitine may be lifesaving in these patients who generally present in infancy.

Interference with fatty acid metabolism also underlies the fasting hypoglycemia associated with Jamaican vomiting sickness, with atractyloside, and with the drug valproate. In *Jamaican vomiting sickness*, the unripe ackee fruit contains a water-soluble toxin, hypoglycin, which produces vomiting, CNS depression, and severe hypoglycemia. The hypoglycemic activity of hypoglycin derives from its inhibition of gluconeogenesis secondary to its interference with the acyl-CoA and carnitine metabolism essential for the oxidation of long-chain fatty acids. The disease is almost totally confined to Jamaica, where ackee forms a staple of the diet for the poor. The ripe ackee fruit no longer contains this toxin. *Atractyloside* is a reagent that inhibits oxidative phosphorylation in mitochondria by preventing the translocation of adenine nucleotides, such as ATP, across the mitochondrial membrane. Atractyloside is a perhydrophenanthrenic glycoside derived from *Atractylis gummifera*. This plant is found in the Mediterranean basin; ingestion of this “thistle” is associated with hypoglycemia and a syndrome similar to Jamaican vomiting sickness. The anticonvulsant drug *valproate* is associated with side effects, predominantly in young infants, which include a Reye-like syndrome, low serum carnitine levels, and the potential for fasting hypoglycemia. In all these conditions, hypoglycemia *is not associated with ketonuria*.

Acute Alcohol Intoxication. The liver metabolizes alcohol as a preferred fuel, and generation of reducing equivalents during the oxidation of ethanol alters the NADH:NAD ratio, which is essential for certain gluconeogenic steps. As a result, gluconeogenesis is impaired and hypoglycemia may ensue if glycogen stores are depleted by starvation or by pre-existing abnormalities in glycogen metabolism. In toddlers who have been unfed for some time, even the consumption of small quantities of alcohol can precipitate these events. The hypoglycemia promptly responds to intravenous glucose, which should always be considered in a child who

presents initially with coma or seizure, after taking a blood sample to determine glucose concentration. The possibility of the child's ingesting alcoholic drinks must also be considered if there was a preceding adult evening party. A careful history allows the diagnosis to be made and may avoid needless and expensive hospitalization and investigation.

Salicylate Intoxication (see also Chapter 704.5). Both hyperglycemia and hypoglycemia occur in children with salicylate intoxication. Accelerated utilization of glucose, resulting from augmentation of insulin secretion by salicylates, and possible interference with gluconeogenesis may contribute to

---

hypoglycemia. Infants are more susceptible than are older children. Monitoring of blood glucose levels with appropriate glucose infusion in the event of hypoglycemia should form part of the therapeutic approach to salicylate intoxication in childhood. Ketosis may occur.

Phosphoenol Pyruvate Carboxykinase Deficiency. Deficiency of this rate-limiting gluconeogenic enzyme is associated with severe fasting hypoglycemia and variable onset after birth. Hypoglycemia may occur within 24?hr after birth, and defective gluconeogenesis from alanine can be documented in vivo. Liver, kidney, and myocardium demonstrate fatty infiltration, and atrophy of the optic nerve and visual cortex may occur. Extensive fatty deposition in liver, kidney, and other tissues also occurs in phosphoenol pyruvate carboxykinase deficiency. Hypoglycemia may be profound. Lactate and pyruvate levels in plasma have been normal, but a mild metabolic acidosis may be present. The fatty infiltration of various organs is caused by increased formation of acetyl-CoA, which becomes available for fatty acid synthesis. Diagnosis of this rare entity can be made with certainty only through appropriate enzymatic determinations in liver biopsy material. Avoidance of periods of fasting through frequent feedings rich in carbohydrate should be helpful because glycogen synthesis and breakdown are intact.

Pyruvate Carboxylase Deficiency (see Chapter 76). This is predominantly a disease of the CNS characterized by a subacute necrotizing encephalomyelopathy and high levels of blood lactate and pyruvate. Hypoglycemia is not a prominent feature of this syndrome, presumably because gluconeogenesis from precursors other than alanine remains intact, and these precursors bypass the pyruvate carboxylase step. The utilization of alanine as well as lactate through pyruvate cannot proceed, however, so these substrates accumulate in blood, and modest hypoglycemia may result during fasting. Affected patients usually die of progressive CNS disease.

OTHER ENZYME DEFECTS

Galactosemia (Galactose-1-Phosphate Uridyl Transferase Deficiency). See Chapter 76 .

Fructose Intolerance (Fructose-1-Phosphate Aldolase Deficiency) (see Chapter 76). Acute hypoglycemia is due to the inhibition by fructose-1-phosphate of glycogenolysis via the phosphorylase system and of gluconeogenesis at the level of fructose-1,6-diphosphate aldolase. Affected individuals usually learn to eliminate fructose from their diet spontaneously.

Defects in Glucose Tranporters

GLUT-1 Deficiency. Two infants with a seizure disorder were found to have low cerebrospinal fluid (CSF) glucose concentrations despite normal plasma glucose. Lactate concentrations in CSF were also low, suggesting decreased glycolysis rather than bacterial infection, which causes low CSF glucose with high lactate. The erythrocyte glucose transporter was defective, suggesting a similar defect in the brain glucose transporter responsible for the clinical features. A ketogenic diet reduced the severity of seizures by supplying an alternate source of brain fuel that bypassed the defect in glucose transport.

GLUT-2 Deficiency. Children with hepatomegaly, galactose intolerance, and renal tubular dysfunction *(Fanconi-Bickel syndrome)* have been shown to have a deficiency of the GLUT-2 glucose transporter of plasma membranes. In addition to liver and kidney tubules, GLUT-2 is also expressed in pancreatic ß cells. Hence, the clinical manifestations reflect impaired glucose release from liver and defective tubular reabsorption of glucose plus phosphaturia and aminoaciduria resulting from *Fanconi syndrome*.

Systemic Disorders. Several systemic disorders are associated with hypoglycemia in infants and children. Neonatal sepsis is often associated with hypoglycemia, possibly as a result of diminished caloric intake with impaired gluconeogenesis. Similar mechanisms may apply to the hypoglycemia found in severely malnourished infants or those with severe malabsorption. Hyperviscosity with a central hematocrit of 65% or greater is associated with hypoglycemia in at least 10–15% of affected infants. *Falciparum malaria* has been associated with hyperinsulinemia and hypoglycemia. Heart and renal failure have also been associated with hypoglycemia, but the mechanism is obscure. Infants and children with *Nissen fundoplication*, a relatively common procedure used to ameliorate gastroesophageal reflux, frequently have an associated “dumping” syndrome with hypoglycemia. Characteristic features include significant hyperglycemia of up to 500?mg/dL 30 minutes postprandially and severe hypoglycemia (average 32?mg/dL in one series) 1.5–3?hr later. The early hyperglycemia phase is associated with brisk and excessive insulin release that causes the rebound hypoglycemia. Glucagon responses have been inappropriately low in some. Although the physiologic mechanisms are not always clearly apparent, and attempted treatments not always effective, *acarbose*, an inhibitor of glucose absorption, has been reported to be successful in one small series.

Diagnosis and Differential Diagnosis.

Table 81–3 lists the pertinent clinical and biochemical findings in the common childhood disorders associated with hypoglycemia. A careful and detailed history is essential in every suspected or documented case of hypoglycemia (see Box 81–5). Specific points to be noted include age at onset, temporal relation to meals or caloric deprivation, and a family history of prior infants known to have had hypoglycemia or of unexplained infant deaths. In the 1st wk of life, the majority of infants have the

transient form of neonatal hypoglycemia either as a result of prematurity/intrauterine growth retardation or by virtue of being born to diabetic mothers. The absence of a history of maternal diabetes, but the presence of macrosomia and the characteristic large plethoric appearance of an “infant of a diabetic mother” should arouse suspicion of hyperinsulinemic hypoglycemia of infancy probably due to a K_{ATP} channel defect that is familial (autosomal recessive) or sporadic; plasma insulin concentrations greater than 10?µU/mL in the presence of documented hypoglycemia confirm this diagnosis. The presence of hepatomegaly should arouse suspicion of an enzyme deficiency; if non–glucose-reducing sugar is present in the urine, galactosemia is most likely. In males, the presence of a microphallus suggests the possibility of hypopituitarism, which also may be associated with jaundice in both sexes.

Past the newborn period, clues to the cause of persistent or recurrent hypoglycemia can be obtained through a careful history, physical examination, and initial laboratory findings. The temporal relation of the hypoglycemia to food intake may suggest that the defect is one of gluconeogenesis, if symptoms occur 6?hr or more after meals. If hypoglycemia occurs shortly after meals, galactosemia or fructose intolerance is most likely, and the presence of reducing substances in the urine rapidly distinguishes these possibilities. The autosomal dominant forms of hyperinsulinemic hypoglycemia need to be considered, with measurement of glucose, insulin, ammonia, and careful history for other affected family members of any age. Measurement of IGFBP-1 may be useful; it is low in hyperinsulinemia states and high in other forms of hypoglycemia. The presence of hepatomegaly suggests one of the enzyme deficiencies in glycogen synthesis or breakdown or in gluconeogenesis, as outlined in Table 81–3 . The absence of ketonemia or ketonuria at the time of initial presentation strongly suggests hyperinsulinemia or a defect in fatty acid oxidation. In most other causes of hypoglycemia, with the exception of galactosemia and fructose intolerance, ketonemia and ketonuria are present at the time of fasting hypoglycemia. At the time of the hypoglycemia, serum should be obtained for determination of hormones and substrates, followed by repeated measurement after an intramuscular or intravenous injection of glucagon, as outlined in Box 81–5 . Interpretation of the findings is summarized in

---

Table 81–3 . Hypoglycemia with ketonuria in children between ages 18 mo and 5 yr is most likely to be ketotic hypoglycemia, especially if hepatomegaly is absent. The ingestion of a toxin, including alcohol or salicylate, can usually be excluded rapidly by the history.

When the history is suggestive but acute symptoms are not present, a 24–36?hr supervised fast can usually provoke hypoglycemia and resolve the question of hyperinsulinemia or other conditions (see Table 81–3). Such a fast is contraindicated if a fatty acid oxidation defect is suspected; other approaches such as mass tandem spectrometry or molecular diagnosis, or both, should be considered. Because adrenal insufficiency may mimic ketotic hypoglycemia, plasma cortisol levels should be determined at the time of documented hypoglycemia; increased buccal or skin pigmentation may provide the clue to primary adrenal insufficiency with elevated ACTH (melanocyte-stimulating hormone) activity. Short stature or a decrease in the growth rate may provide the clue to pituitary insufficiency involving growth hormone as well as ACTH. Definitive tests of pituitary-adrenal function such as the arginine-insulin stimulation test for growth hormone IGF-1, IGFBP-1, and cortisol release may be necessary.

In the presence of hepatomegaly and hypoglycemia, a presumptive diagnosis of the enzyme defect can often be made through the clinical manifestations, presence of hyperlipidemia, acidosis, hyperuricemia, response to glucagon in the fed and fasted states, and the response to infusion of various appropriate precursors (see Table 81–3 and Box 81–5). These clinical findings and investigative approaches are summarized in Table 81–3 . Definitive diagnosis of the glycogen storage disease may require an open liver biopsy (see Chapter 76). Occasional patients with all the manifestations of glycogen storage disease are found to have normal enzyme activity. These definitive studies require special expertise available only in certain institutions.

Treatment.

The prevention of hypoglycemia and its resultant effects on CNS development are important in the newborn period. For neonates with hyperinsulinemia not associated with maternal diabetes, subtotal pancreatectomy may be needed, unless hypoglycemia can be readily controlled with long-term somatostatin analogues or diazoxide.

Treatment of acute symptomatic neonatal or infant hypoglycemia includes intravenous administration of 2?mL/kg of D_{10} W, followed by a continuous infusion of glucose at 6–8?mg/kg/min, adjusting the rate to maintain blood glucose levels in the normal range.

The management of persistent neonatal or infantile hypoglycemia includes increasing the rate of intravenous glucose infusion to 8–15?mg/kg/min or more, if needed. This may require a central venous or umbilical venous catheter to administer a hypertonic 15–20% glucose solution. If hyperinsulinemia is present, it should be managed with diazoxide, somatostatin analogues, or calcium channel blockers. In addition, intramuscular or intravenous hydrocortisone, 5?mg/kg/24?hr given in divided doses every 8?hr, or oral prednisone, 1–2?mg/kg/24?hr given in divided doses every 6–12?hr, and intramuscular growth hormone, 1?mg/24?hr, may be added temporarily if hypoglycemia is unresponsive to intravenous glucose; if ineffective, these medications should be discontinued after 3–5 days.

Oral diazoxide, 10–25?mg/kg/24?hr given in divided doses q6h, may reverse hyperinsulinemic hypoglycemia but also may produce hirsutism, edema, nausea, hyperuricemia, electrolyte disturbances, advanced bone age, IgG deficiency, and, rarely, hypotension with prolonged use. A long-acting somatostatin analogue (octreotide, formerly SMS 201–995) is effective in controlling hyperinsulinemic hypoglycemia in patients with islet cell disorders not caused by genetic mutations in K_{ATP} channel and islet cell adenoma. Octreotide is administered subcutaneously every 6–12?hr in doses of 20–50?µg in neonates and young infants. Potential but unusual complications include poor growth due to inhibition of growth hormone release, pain at the injection site, vomiting, diarrhea, and hepatic dysfunction (hepatitis, cholelithiasis). Octreotide is usually employed as a temporizing agent for

various periods before subtotal pancreatectomy for K_{ATP} channel disorders. It may be particularly useful for the treatment of refractory hypoglycemia despite subtotal pancreatectomy. Total pancreatectomy is not optimal therapy, owing to the risks of surgery, permanent diabetes mellitus, and exocrine pancreatic insufficiency. Continued prolonged medical therapy without pancreatic resection if hypoglycemia is controllable is worthwhile because some children have a spontaneous resolution of the hyperinsulinemic hypoglycemia. This should be balanced against the risk of hypoglycemia-induced CNS injury and the toxicity of drugs.

Part 11 - The Fetus and the Neonatal Infant

Section 1 - *Noninfectious Disorders*

Chapter 82 - Overview of Mortality and Morbidity

Barbara J. Stoll
Robert M. Kliegman

Fetal and extrauterine life form a continuum during which human growth and development are affected by genetic, environmental, and social factors. The perinatal period is most often defined as the period from the 28th wk of gestation through the 7th day after birth (additional definitions include the 20th wk of gestation to the 7th day and the 20th wk of gestation to the 28th day). The neonatal period is defined as less than 28 days of life and may be further subdivided into period 1, birth to less than 24?hr; period 2, 24?hr to less than 7 days; and period 3, 7 days to less than 28 days.

Perinatal mortality is influenced by prenatal, maternal, and fetal conditions and by circumstances surrounding delivery. Perinatal deaths are associated with intrauterine growth restriction (IUGR); conditions that predispose the fetus to asphyxia, such as placental insufficiency; severe congenital malformations; and overwhelming early-onset neonatal infections (Table 82–1). Major causes of neonatal mortality are diseases associated with preterm birth and low birthweight (LBW) and lethal congenital anomalies. Neonatal mortality is highest during the first 24?hr of life and overall accounts for 65% of all infant deaths (i.e., deaths before 1 yr of age). Between 1980 and 2000, neonatal mortality rates in the United States declined 46% to 4.6 per 1,000 live births (Fig. 82–1). Factors related to the decline include improved obstetric and neonatal management with a significant reduction in birthweight-specific neonatal mortality (Fig. 82–2). Further reduction in neonatal mortality will depend on prevention of preterm delivery and LBW, prenatal diagnosis and early management of congenital anomalies, and timely effective treatment of diseases that result from factors in gestation and during labor and delivery (see Table 82–1).

In the United States each year, approximately 6 million pregnancies, 4 million live births, 18,000 neonatal deaths, and 28,000 infant deaths occur. Twelve per cent of births are to teenage women between the ages of 15 and 19 yr; 33% are to unmarried women. Births among teenagers (especially first births) declined 22% between 1991 and 2000 (Fig. 82–3). Births to unmarried women remain stable.

Infant mortality rates (deaths occurring from birth to 12 mo of age per 1,000 live births) vary by country; in 1998, rates were lowest in Hong Kong (3.2/1,000 births), moderate in the United States (7.2/1,000), and highest in developing countries (30–150/1,000). Medical, socioeconomic, and cultural factors influence perinatal and neonatal mortality. Preventive variables such as health education, prenatal care, nutrition, social support, risk identification, and obstetric care can effectively reduce perinatal and neonatal mortality. In the United States, 50% of

Umbilical cord accident	Congenital anomalies	Persistent pulmonary hypertension (PPHN)
Abruptio placentae	Infection	
Hydrops fetalis	Necrotizing enterocolitis Bronchopulmonary dysplasia (BPD)	

infant deaths in 2000 were due to four causes (classified according to the International Classification of Diseases, 10th edition): congenital malformations, disorders relating to prematurity and unspecified LBW, sudden infant death syndrome (SIDS), and newborns affected by maternal complications of pregnancy.

Figure 82-1 Infant, neonatal, and postneonatal mortality, LBW and VLBW, and preterm delivery, United States, 1980–2000. IMR = infant deaths per 1,000 live births; NMR = neonatal deaths per 1,000 live births; PNMR = postneonatal deaths per 1,000 live births; LBW = percent low birthweight (<2500?g); VLBW = percent very low birthweight (<1500?g); PT = percent preterm (<37 weeks' gestation). (From Hoyert DL, Freedman MA, Strobino DM, Guyer B: Annual summary of vital statistics: 2000. *Pediatrics* 2001;108:1241.)

Figure 82-2 Neonatal mortality, by birthweight categories, for black (*filled circles*) and for white (*open circles*) infants in the United States. *Solid lines* denote data for 1989; *dashed lines* are for 1997. Data shown are for births of newborn infants weighing less than 2,250?g only. (From Demissie K, Rhoads GG, Ananth CV, et al: Trends in preterm birth and neonatal mortality among Blacks and Whites in the United States from 1989 to 1997. *Am J Epidemiol* 2001;154:307.)

LBW (as a result of preterm delivery and/or IUGR) is a major determinant of both neonatal and infant mortality rates and, together with congenital anomalies (e.g., cardiac, central nervous system, and respiratory), contributes significantly to childhood

Figure 82-3 Birthrates for teenagers by age: United States, 1950–2000. (From Ventura SJ, Mathews TJ, Hamilton BE: Births to teenagers in the United States, 1940–2000. *Natl Vital Stat Rep* 2001;49:1.)

morbidity. The LBW rate is directly related to the variance of infant mortality rates among different countries.

The *LBW rate* (infants weighing 2,500?g or less at birth each year) in the United States increased from 6.6% to 7.6% between 1981 and 2000, whereas the very low birthweight (VLBW) rate (infants weighing 1,500?g or less at birth) increased from 1.1% to 1.4% of all births. In the past decade, LBW has increased in white infants, mainly because of an increase in multiple births (often associated with assisted reproduction), whereas in blacks, LBW has decreased (Fig. 82–4). Nonetheless, LBW and VLBW rates remain highest among black infants. Reasons for the racial disparity in LBW remain unclear. Despite advances in prenatal and obstetric care, racial disparity in birthweight persists, thus suggesting the need for novel prevention programs. Furthermore, although preterm LBW survival is better among black neonates (see Fig. 82–2), overall neonatal and infant mortality rates remain highest in blacks (Fig. 82–5), even those born to extremely low-risk mothers (married, aged 20–34 yr, =13 yr of education, adequate prenatal care, no medical risk factors, no alcohol or tobacco use during pregnancy). A reduction in the racial disparity in mortality is an important public health issue reflected in the U.S. National Health Objectives for the Year 2010.

LBW is caused by preterm birth, IUGR, or both factors. The predominant cause of LBW in the United States is preterm birth, whereas in developing countries, the cause is more often IUGR. Although IUGR does not appear to further increase the risk of mortality in preterm infants, both morbidity and mortality are increased in term growth-restricted infants. VLBW infants are most often premature (<37 wk of gestation), although IUGR may also complicate their early delivery. Even though VLBW occurs in only 1–2% of all infants in the United States, these births represent a large proportion of the neonatal and infant mortality and infants with both short- and long-term complications, including neurodevelopmental handicaps. The etiology of

Figure 82-4 Percent low birthweight by race and ethnicity, selected years: United States, 1950–1999. (From Guyer B, Freedman MA, StrobinoDM, et al: Annual summary of vital statistics: Trends in the health of Americans during the 20th century. *Pediatrics* 2000; 106:1307.)

preterm birth is complex, multifactorial, and not completely understood. Causes include maternal diseases such as severe preeclampsia requiring elective delivery, premature rupture of membranes, uterine abnormalities, placental bleeding (abruptio, previa), multifetus gestation, drug misuse, maternal chronic illnesses, fetal distress, and infection. A complex interaction can be noted between infection, inflammation, and both preterm premature rupture of membranes and preterm birth. Infectious

Figure 82-5 Infant mortality rates by race and ethnicity, 1998. (From Mathews TJ, Curtin SC, MacDorman MF: Infant mortality statistics from the 1998 period linked birth/infant death data set. *Natl Vital Stat Rep* 2000; 48:1.)

antecedents include maternal urinary tract infection, pyelonephritis, chorioamnionitis, bacterial vaginosis, and upper and lower genitourinary tract infection with a variety of agents (*Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Gardnerella vaginalis*, and group B streptococcus). In many cases, the cause of preterm delivery is unknown.

Although 99% of births occur in hospitals, only 83% of pregnant women receive

prenatal care in the 1st trimester. Many

women who receive inadequate prenatal care are at risk for perinatal complications. Barriers to prenatal care include absent or insufficient money or insurance to pay for care; poor coordination of services, including language and cultural issues; and inadequate effective education about the importance of prenatal care. Successful and adequate provision of high-quality prenatal care requires competent health care professionals and coordination of services among physicians' offices, clinics, community hospitals, special regionalized programs for high-risk mothers and infants, and tertiary care centers. Regional perinatal programs should provide continuing education and consultation in both the community and the referral center and transportation for pregnant women and newborn infants to appropriate hospitals; they should also include a regional hospital with facilities, equipment, and personnel for obstetric and neonatal intensive care (Table 82–2).

Fetal deaths slightly exceed neonatal deaths in their contribution to perinatal mortality. Obstetricians have a central role in reducing perinatal mortality and morbidity. Intrapartum fetal deaths have declined more than antepartum fetal deaths; this decline may reflect an increase in the use of fetal monitoring during labor and more liberal use of cesarean section for fetal distress and other obstetric complications. It is important to emphasize the need to be able to predict the maturity and functional reserve of a fetus both before and during labor so that fetuses and infants at greatest risk can be identified as early as possible. The obstetrician and pediatrician must effectively interact to anticipate perinatal problems and take prompt preventive and therapeutic measures.

Postneonatal mortality refers to deaths between 28 days and 1 yr of life. Historically, these infant deaths were due to causes outside the neonatal period, such as SIDS, infections (respiratory, enteric), and trauma. With the advent of modern neonatal care, many VLBW infants who would have died in the 1st mo of life now survive the neonatal period only to succumb to the sequelae noted in Table 82–3 . This delayed neonatal mortality is an important contributor to postneonatal mortality.

For the most immature infants at the limit of viability (22–25 wk gestation), decision-making regarding care is a complex process that involves the physician and other health professionals, the family, and society. The challenge is to not only improve survival but also reduce short-term complications and improve long-term neurodevelopmental outcome.

Adverse neurodevelopmental sequelae include cerebral palsy, seizures, hydrocephalus requiring a shunt, blindness, deafness,

TABLE 82-2 -- **Levels of In-Hospital Perinatal Care**

Basic	
Maternal	***Neonate***
Monitor and care for low-risk patients	Resuscitation
	Stabilization
Triage for high risk for transfer	Well neonatal care
Detection and care of unanticipated labor problems	Nursery care
	Visitation
Emergency cesarean delivery within 30 min	General pediatrician staff (capable of neonatal resuscitation)
Blood bank, anesthesia, radiology, ultrasound, and laboratory support	
Care of postpartum problems Obstetrician, nurse, midwife staff	
Special Care	
Maternal	***Neonate***

TABLE 82-3 -- **Morbidities and Sequelae of Perinatal and Neonatal Illness**

Morbidities	Examples	Morbidities	Examples
Central Nervous System		***Sensation-Peripheral Nerves***	
Spastic diplegic-quadriplegic cerebral palsy	Hypoxic-ischemic encephalopathy, periventricular leukomalacia, undetermined antenatal factors	Reduced visual acuity (blindness)	Retinopathy of prematurity (ROP)
		Strabismus	Undetermined
		Hearing impairment (deafness)	Drug toxicity (furosemide, aminoglycosides), bilirubin encephalopathy, hypoxia ± hyperventilation
Choreoathetotic cerebral palsy	Bilirubin encephalopathy (kernicterus)		
Microcephaly	Hypoxic-ischemic encephalopathy, intrauterine infection (rubella, CMV)		
Communicating hydrocephalus	Intraventricular hemorrhage, meningitis	Poor speech	Immaturity, chronic illness, hypoxia, prolonged endotracheal intubation, hearing deficit
Seizures	Hypoxic-ischemic encephalopathy, hypoglycemia		
Encephalopathy	Congenital infections (rubella, CMV, human immunodeficiency virus, toxoplasmosis)	Paralysis-paresis	Birth trauma-brachial plexus, phrenic nerve, spinal cord
Educational failure and/or mental retardation	Immaturity, low socioeconomic status, hypoxia, hypoglycemia, cerebral palsy, intraventricular hemorrhage		

Respiratory		***Gastrointestinal***	Necrotizing enterocolitis, gastroschisis, malrotation-volvulus, cystic fibrosis, intestinal atresia
Bronchopulmonary dysplasia (BPD)	Oxygen toxicity, barotrauma	Short-gut syndrome	
Subglottic stenosis	Endotracheal tube injury		
Sudden infant death syndrome	Prematurity, BPD, infant of illicit drug user	Cholestatic liver disease (cirrhosis, hepatic failure)	Hyperalimentation toxicity, sepsis, short-gut syndrome
Choanal stenosis, nasal septum destruction	Nasotracheal intubation		
	Growth failure	Failure to thrive	Short-gut syndrome, cholestasis, BPD, cerebral palsy, severe congenital heart disease
Cardiovascular			
Cyanosis	Precorrective palliative care of congenital cyanotic heart disease, cor pulmonale from BPD, reactive airway	Poor postnatal weight gain	
		Inguinal hernia	Unknown
		Miscellaneous	
Heart failure	Precorrective palliative care of complex congenital heart disease, BPD, ventricular septal defect	Cutaneous scars	Chest tube or IV placement, hyperalimentation, subcutaneous infiltration, fetal puncture, intrauterine varicella, cutis aplasia
		Absent radial artery pulse	
		Hypertension	Frequent arterial puncture
			Renal thrombi, repair of coarctation of aorta

CMV = cytomegalovirus; BPD = bronchopulmonary dysplasia; ROP = retinopathy of prematurity

and cognitive impairment. The risk of an adverse outcome increases with decreasing gestational age at birth. Early morbidity and prognostic variables that contribute to adverse neurodevelopmental outcomes include grades 3–4 intraventricular hemorrhage and periventricular leukomalacia, necrotizing enterocolitis requiring extensive bowel resection, bronchopulmonary dysplasia, and postnatal steroid therapy. The association of postnatal steroid use with adverse neurodevelopmental outcome highlights the importance of high-risk infant follow-up after hospital discharge to assess the long-term impact of new and/or frequently used therapies. Many studies have documented the impact of social and family risk factors on outcome. At school age, VLBW infants have poorer physical growth, cognitive function, and school performance. These disadvantages appear to persist into adulthood and therefore have broad implications for society. All VLBW infants must be monitored after discharge to detect neurodevelopmental impairment as early as possible and to ensure that children and families receive any interventions available and adequate support to optimize long-term outcome. **REFERENCES**

Chapter 83 - The Newborn Infant (see also Chapter 9)

Barbara J. Stoll
Robert M. Kliegman

The neonatal period is a highly vulnerable time for an infant, who is completing many of the physiologic adjustments required for extrauterine existence. The high neonatal morbidity and mortality rates attest to the fragility of life during this period; in the United States, of all deaths occurring in the 1st yr, two thirds are in the neonatal period. The annual rate of deaths during the 1st yr is unequaled until the 7th decade.

An infant's transition from intrauterine to extrauterine life requires many biochemical and physiologic changes. No longer dependent on maternal circulation via the placenta, a newborn's pulmonary function is activated for self-sufficient respiratory exchange of oxygen and carbon dioxide. Newborn infants also become dependent on gastrointestinal tract function for absorbing food, renal function for excreting waste and maintaining chemical homeostasis, hepatic function for neutralizing and excreting toxic substances, and function of the immunologic system for protecting against infection. The neonatal cardiovascular and endocrine systems also adapt for self-sufficient functioning. Many of a newborn infant's special problems are related to poor adaptation because of asphyxia, premature birth, life-threatening congenital anomalies, or the adverse effects of delivery.

83.1 History in Neonatal Pediatrics

The neonatal history should (1) identify disabling diseases that are amenable to prompt preventive action or treatment (e.g., respiratory distress syndrome),

(2) anticipate conditions that may be of later importance (e.g., gonococcal conjunctivitis), and (3) uncover possible causative factors that may explain pathologic conditions regardless of their immediate or future significance (e.g., screening for inborn errors of metabolism). The perinatal history should include demographic and social data (socioeconomic status, age, race); past medical

illnesses in the family, including siblings (cardiopulmonary disorders, infectious diseases, genetic disorders, anemia, jaundice, diabetes mellitus); previous maternal reproductive problems (stillbirth, prematurity, blood group sensitization); events occurring in the present pregnancy (vaginal bleeding, medications, acute illness, duration of rupture of membranes); and a description of the labor (duration, fetal presentation, fetal distress, fever) and delivery (cesarean section, anesthesia or sedation, use of forceps, Apgar score, need for resuscitation).

83.2 Physical Examination of the Newborn Infant

Many physical and behavioral characteristics of a normal newborn infant are described in Chapter 9 , which should be reviewed.

The initial examination of a newborn infant should be performed as soon as possible after delivery to detect abnormalities and to establish a baseline for subsequent examination. Infants should have temperature, pulse, respiratory rate, color, type of respiration, tone, activity, and level of consciousness monitored every 30?min after birth for 2?hr or until stabilized. For high-risk deliveries, this examination should take place in the delivery room and focus on congenital anomalies and pathophysiologic problems that may interfere with normal cardiopulmonary and metabolic adaptation to extrauterine life. Congenital anomalies may be present in 3–5% of infants. After a stable delivery room course, a 2nd and more detailed examination should be performed within 24?hr of birth. If an infant remains in the hospital longer than 48?hr, a discharge examination should be performed within 24?hr of discharge. With a healthy infant, the mother should be present during this examination; even minor, seemingly insignificant anatomic variations may worry a family and should be explained. The explanation must be careful and skillful so that otherwise unworried families are not unduly alarmed. No infant should be discharged from the hospital without a final examination because certain abnormalities, particularly heart murmurs, often appear or disappear in the immediate neonatal period and, in addition, evidence of disease that has just been acquired may be noted. The pulse (normal, 120–160 beats/min), respiratory rate (normal, 30–60 breaths/min), temperature, weight, length, head circumference, and dimensions of any visible or palpable structural abnormality should be recorded. Blood pressure is determined if a neonate appears ill or has a heart murmur.

Examining a newborn requires patience, gentleness, and procedural flexibility. Thus, if the infant is quiet and relaxed at the beginning of the examination, palpation of the abdomen or auscultation of the heart should be performed first before other, more disturbing manipulations are attempted.

General Appearance.

Physical activity may be absent during the relaxation of normal sleep, or it may be decreased by the effects of illness or drugs; an infant may be either lying with the extremities motionless, to conserve energy for the effort of difficult breathing, or be vigorously crying with accompanying activity of the arms and legs. Both active and passive muscle tone and any unusual posture should be recorded. Coarse, tremulous movements with ankle or jaw myoclonus are more common and less significant in newborn infants than at any other age. Such movements tend to occur when an infant is active, whereas convulsive twitching usually occurs in a quiet state. Edema may produce a superficial appearance of good nutrition. Pitting after applied pressure may or may not be noted, but the skin of the fingers and toes lacks the normal fine wrinkles when filled with fluid. Edema of the eyelids commonly results from irritation caused by the administration of silver nitrate. Generalized edema may occur with prematurity, hypoproteinemia secondary to severe erythroblastosis fetalis, nonimmune hydrops, congenital nephrosis, Hurler syndrome, or unknown cause. Localized edema suggests a congenital malformation of the lymphatic system; when confined to one or more extremities of a female infant, it may be the initial sign of Turner syndrome (Chapters 70 and 580.1).

Skin.

Vasomotor instability and peripheral circulatory sluggishness are revealed by deep redness or purple lividity in a crying infant, whose color may darken profoundly with closure of the glottis preceding a vigorous cry, and by harmless cyanosis (acrocyanosis) of the hands and feet, especially when they are cool. Mottling, another example of general circulatory instability, may be associated with serious illness or related to a transient fluctuation in skin temperature. An extraordinary division of the body from the forehead to the pubis into red and pale halves is known as harlequin color change, a transient and harmless condition. Significant *cyanosis* may be masked by the pallor of circulatory failure or anemia; alternatively, the relatively high hemoglobin content of the first few days and the thin skin may combine to produce an appearance of cyanosis at a higher Pa_{O_2} than in older children. Localized cyanosis is differentiated from ecchymosis by the momentary blanching pallor (with cyanosis) that occurs after pressure. The same maneuver also helps in demonstrating *icterus*, possibly significant but unnoticed if the skin is suffused with blood. *Pallor* may represent asphyxia, anemia, shock, or edema. Early recognition of anemia may lead to a diagnosis of erythroblastosis fetalis, subcapsular hematoma of the liver or spleen, subdural hemorrhage, or fetal-maternal or twin-twin transfusion. Without being anemic, postmature infants tend to have paler and thicker skin than term or premature infants do. The ruddy red appearance of *plethora* is seen with polycythemia.

The vernix and common transitory macular capillary hemangiomas of the eyelids and neck are described in Chapter 637 . Cavernous hemangiomas are deeper, blue masses that if large, may trap platelets and produce disseminated intravascular coagulation or interfere with local organ function. Scattered petechiae may be seen on the presenting part (usually the scalp or face) after a difficult delivery. Slate blue, well-demarcated areas of pigmentation are seen over the buttocks, back, and sometimes other parts of the body in more than 50% of black, Native American, or Asian infants and occasionally in white ones. These patches have no known anthropologic significance despite their name **mongolian spots**; they tend to disappear within the first year. The vernix, skin, and especially the cord may be stained brownish yellow if the amniotic fluid has been colored by the passage of meconium during or before birth.

The skin of premature infants is thin and delicate and tends to be deep red; in extremely premature infants, the skin appears almost gelatinous and bleeds and bruises easily. Fine, soft, immature hair—**lanugo**—frequently covers the scalp and brow and may also cover the face of premature infants. Lanugo has usually been lost or replaced by vellus hair in term infants. Tufts of hair over the lumbosacral spine suggest an underlying abnormality such as occult spina bifida, a sinus tract, or a tumor. The nails are rudimentary in very premature infants, but they may protrude

beyond the fingertips in infants born past term. Post-term infants may have a peeling, parchment-like skin (Fig. 83–1), a severe degree of which suggests ichthyosis congenita (Chapter 637).

Figure 83.2-1 Infant with intrauterine growth retardation as a result of placental insufficiency. Note the long, thin appearance with peeling, parchment-like dry skin, alert expression, meconium staining of the skin, and long nails. (From Clifford S: *Advances in Pediatrics*, Vol 9. Chicago, Year Book, 1962.)

In many neonates, small, white, occasionally vesiculopustular papules on an erythematous base develop 1–3 days after birth. This benign rash, *erythema toxicum*, persists for as long as 1 wk, contains eosinophils, and is usually distributed on the face, trunk, and extremities (Chapter 637). *Pustular melanosis*, a benign lesion seen predominantly in black neonates, contains neutrophils and is present at birth as a vesiculopustular eruption around the chin, neck, back, extremities, and palms or soles; it lasts 2–3 days. Both lesions need to be distinguished from more dangerous vesicular eruptions such as herpes simplex (Chapter 231) and staphylococcal disease of the skin (Chapter 166.1).

Amniotic bands may disrupt the skin, extremities (amputation, ring constriction, syndactyly), face (clefts), or trunk (abdominal or thoracic wall defects). Their cause is uncertain but may be related to amniotic membrane rupture or vascular compromise with fibrous band formation. Excessive skin fragility and extensibility with joint hypermobility suggest Ehlers-Danlos syndrome, Marfan syndrome, congenital contractural arachnodactyly, or other disorders of collagen synthesis.

Skull.

All infants should have their head circumference noted on the chart. The skull may be molded, particularly if the infant is the first-born and if the head has been engaged for a considerable time. The parietal bones tend to override the occipital and frontal bones. The head of an infant born by cesarean section or from a breech presentation is characterized by its roundness. The suture lines and the size and tension of the anterior and posterior fontanels should be determined digitally. Premature fusion of sutures (cranial synostosis) is identified by a hard non-movable ridge over the suture and an abnormally shaped skull. Great variation in the size of the fontanels exists at birth; if small, the anterior fontanel usually tends to enlarge during the first few months of life. The persistence of excessively large anterior (normal, 20 ± 10?mm) and posterior fontanels has been associated with several disorders (Box 83–1). Persistently small fontanels suggest microcephaly, craniosynostosis, congenital hyperthyroidism, or wormian bones; a 3rd fontanel suggests trisomy 21 but is seen in preterm infants. Soft areas (craniotabes) are occasionally found in the parietal bones at the vertex near the sagittal suture; they are more common in premature infants and in infants who have been exposed to uterine compression. Though usually insignificant, their possible pathologic cause should be investigated if they persist. Soft areas in the occipital region suggest the irregular calcification and wormian bone formation associated with osteogenesis imperfecta, cleidocranial dysostosis, lacunar skull, cretinism, and occasionally, Down syndrome. Transillumination of an abnormal skull in a dark room or examination by ultrasound or computed tomography rules out hydranencephaly or hydrocephaly (Chapter 585). An excessively large head (megalencephaly) suggests hydrocephaly, storage disease, achondroplasia, cerebral gigantism, neurocutaneous syndromes, or inborn errors of metabolism, or it may be familial. The skull of a premature infant may suggest hydrocephaly because of the relatively larger brain growth in comparison to that of other organs. Depression of the skull (indentation, fracture, Ping-Pong ball deformity) is usually of prenatal onset from prolonged focal pressure by the bony pelvis. Atrophic or alopecic scalp areas may represent *aplasia cutis congenita*, which may be sporadic or autosomal dominant or be associated with trisomy 13, chromosome 4 deletion, or Johanson-Blizzard syndrome. Deformational plagiocephaly may be due to in utero positioning forces on the skull and is manifested as an asymmetric skull and face with ear malalignment. It is associated with torticollis and vertex positioning.

Face.

The general appearance should be noted with regard to dysmorphic features, such as epicanthal folds, widely spaced eyes, microphthalmos, asymmetry, long philtrum, and low-set ears, which are often associated with congenital syndromes. The face may be asymmetric as a result of a 7th nerve palsy, hypoplasia of the depressor muscle at the angle of the mouth, or an abnormal fetal posture (Chapter 97); when the jaw has been held against a shoulder or an extremity during the intrauterine period, the mandible may deviate strikingly from the midline. Symmetric facial palsy suggests absence or hypoplasia of the 7th nerve nucleus (Möbius syndrome).

EYES.

The eyes often open spontaneously if the infant is held up and tipped gently forward and backward. This maneuver, a result of labyrinthine and neck reflexes, is more successful for inspecting the eyes than forcing the lids apart is. *Conjunctival and retinal hemorrhages* are usually benign. Retinal hemorrhages are more common with vacuum-assisted deliveries (75%) than after cesarean section (7%). They resolve in most infants by 2 wk (85%) and in all infants by 4 wk of age. Pupillary reflexes are present after 28–30 wk of gestation. The iris should be inspected for colobomas and heterochromia. A cornea larger than 1?cm in diameter in a term infant (and photophobia and tearing) suggests

Box 83.2-1. Disorders Associated with a Large Anterior Fontanel

- Achondroplasia
- Apert syndrome
- Athyrotic hypothyroidism
- Cleidocranial dysostosis
- Congenital rubella syndrome
- Hallermann-Streiff syndrome

- Osteogenesis imperfecta
- Prematurity
- Pyknodysostosis
- Russell-Silver syndrome
- 13-, 18-, 21-trisomies
- Vitamin D deficiency rickets

---

congenital glaucoma and requires prompt ophthalmologic consultation. The presence of bilateral *red reflexes* suggests the absence of cataracts and intraocular pathology (Chapters 610 , 618–624). Leukokoria (white pupillary reflex) suggests cataracts, tumor, chorioretinitis, retinopathy of prematurity, or a persistent hyperplastic primary vitreous and warrants an immediate ophthalmologic consultation.

EARS.

Deformities of the pinnae are occasionally seen. Unilateral or bilateral preauricular skin tags occur frequently; if pedunculated, they can be tightly ligated at the base, and dry gangrene and sloughing result. The tympanic membrane, easily seen otoscopically through the short, straight external auditory canal, normally appears dull gray.

NOSE.

The nose may be slightly obstructed by mucus accumulated in the narrow nostrils. The nares should be symmetric and patent. Dislocation of the nasal cartilage from the vomerian groove results in asymmetric nares.

MOUTH.

A normal mouth may rarely have precocious dentition, with natal (present at birth) or neonatal (eruption after birth) *teeth* in the lower incisor position or aberrantly placed; these teeth are shed before the deciduous ones erupt. Alternatively, such teeth occur in Ellis-van Creveld, Hallermann-Streiff, and other syndromes. Extraction is not usually indicated. Premature eruption of deciduous teeth is even more unusual. The **soft** and **hard palate** should be inspected and palpated for a complete or submucosal cleft and the contour noted if the arch is excessively high or the uvula is bifid. On the hard palate on either side of the raphe may be temporary accumulations of epithelial cells called **Epstein pearls.** Retention cysts of similar appearance may also be seen on the gums. Both disappear spontaneously, usually within a few weeks of birth. Clusters of small white or yellow follicles or ulcers on an erythematous base may be found on the anterior tonsillar pillars, most frequently on the 2nd–3rd day of life. Of unknown cause, they clear without treatment in 2–4 days.

Neonates do not have active salivation. The **tongue** appears relatively large; the **frenulum** may be short, but rarely, if ever is shortness a reason for cutting it. The sublingual mucous membrane occasionally forms a prominent fold. The **cheeks** have a fullness on both the buccal and the external aspects as a result of the accumulation of fat making up the **sucking pads.** These pads, as well as the labial tubercle on the upper lip (sucking callus), disappear when suckling ceases. A marble-sized buccal mass is usually due to benign idiopathic fat necrosis.

The **throat** of a newborn infant is hard to see because of the low arch of the palate; however, it should be clearly viewed because it is easy to miss posterior palatal or uvular clefts. The tonsils are small.

Neck.

The neck appears relatively short. Abnormalities are not common but include goiter, cystic hygroma, branchial cleft rests, teratoma, hemangioma, and lesions of the sternocleidomastoid muscle that are presumably traumatic or due to a fixed positioning in utero that produces either a hematoma or fibrosis, respectively. *Congenital torticollis* causes the head to turn toward and the face to turn away from the affected side. Plagiocephaly, facial asymmetry, and hemihypoplasia may develop if it is untreated (see Chapter 670.1). Redundant skin or webbing in a female infant suggests intrauterine lymphedema and Turner syndrome (Chapter 580.1). Both

clavicles should be palpated for fractures.

Chest.

Breast hypertrophy is common, and milk may be present (but should not be expressed). Asymmetry, erythema, induration, and tenderness should suggest mastitis or a breast abscess. Look for supernumerary nipples, inverted nipples, or widely spaced nipples with a shield-shaped chest; the latter suggests Turner syndrome.

Lungs.

Much can be learned by observing breathing. Variations in rate and rhythm are characteristic and fluctuate according to the infant's physical activity, state of wakefulness, or the presence of crying. Because fluctuations are rapid, the respiratory rate should be counted for a full minute with the infant in the resting state, preferably asleep. Under these circumstances, the usual rate for normal term infants is 30–40/min; in premature infants the rate is higher and fluctuates more widely. A rate consistently over 60/min during periods of regular breathing usually indicates pulmonary, cardiac, or metabolic disease. Premature infants may breathe with a Cheyne-Stokes rhythm, known as periodic respiration, or with complete irregularity. Irregular gasping, sometimes accompanied by spasmodic movements of the mouth and chin, strongly indicates serious impairment of the respiratory centers.

The breathing of newborn infants is almost entirely diaphragmatic, so during inspiration the soft front of the thorax is usually drawn inward while the abdomen protrudes. If the baby is quiet, relaxed, and of good color, this “paradoxical movement” does not necessarily signify insufficient ventilation. On the other hand, labored respiration is important evidence of respiratory distress syndrome, pneumonia, anomalies, or mechanical disturbance of the lungs. A weak persistent or intermittent groaning, whining cry or **grunting** during expiration signifies potentially serious cardiopulmonary disease or sepsis and warrants immediate attention. When benign, the grunting resolves between 30 and 60?min after birth. Flaring of the alae nasi and retraction of the intercostal muscles and sternum are common signs of pulmonary pathology.

Normally, the breath sounds are bronchovesicular. Suspicion of pulmonary pathology because of diminished breath sounds, rales, or percussion dullness should always be verified with a chest radiograph.

Heart.

Normal variation in the size and shape of the chest makes it difficult to estimate the size of the heart. The location of the heart should be determined to detect dextrocardia. Transitory benign murmurs are common. Congenital heart disease may not initially produce the murmur that will appear later; only a Z/zx chance exists that a murmur heard at birth represents congenital heart disease. Evaluation of the heart by roentgenography, echocardiography, and electrocardiography is essential when the possibility of a significant lesion exists. The pulse may vary normally from 90/min in relaxed sleep to 180/min during activity. The still higher rate of supraventricular tachycardia (>220) may be determined better on a cardiac monitor or electrocardiogram than by ear. Premature infants, whose resting heart rate is usually 140–150/min, may have a sudden onset of sinus bradycardia. Pulses should be palpated in the upper and lower extremities to detect coarctation of the aorta on both admission and discharge from the nursery.

Blood pressure measurements may be a valuable diagnostic aid in ill infants (Chapter 418). The *oscillometric method* is the easiest and most accurate noninvasive method available. Continuous or intermittent direct measurement of blood pressure with an umbilical artery catheter may be indicated in special circumstances for infants who are under close observation in an intensive care unit (Fig. 83–2).

Abdomen.

The liver is usually palpable, sometimes as much as 2?cm below the rib margin. Less commonly, the tip of the spleen may be felt. The approximate size and location of each kidney can usually be determined on deep palpation. At no other period of life does the amount of air in the gastrointestinal tract vary so much, nor is it usually so great under normal circumstances. Gas should normally be present in the rectum on roentgenogram by 24?hr of age. The abdominal wall is normally weak (especially in premature infants), and diastasis recti and umbilical hernias are common, particularly in black infants.

Unusual masses should be investigated immediately by ultrasonography. Renal pathology is the cause of most neonatal abdominal masses. Cystic abdominal masses include hydronephrosis, multicystic-dysplastic kidneys, adrenal hemorrhage,

Figure 83.2-2 Nomogram for mean blood pressure (BP) in neonates with gestational ages of 23–43 wk derived from continuous arterial BP measurements obtained from 103 infants admitted to the neonatal intensive care unit. The graph shows the predicted mean BP of neonates of different gestational age during the first 72 hours of life. Each line represents the lower limit of the 80% confidence interval (two-tail) of the mean BP for each gestational age group; 90% of infants for each gestational age group will be expected to have a mean BP value equal to or above the value indicated by the corresponding line, the lower limit of the confidence interval. (From Nuntnarumit P, Yang W, Bada-Ellzey SB: Blood pressure measurements in the newborn. *Clin Perinatol* 1999;26:981–96.)

hydrometrocolpos, intestinal duplication, and choledochal, ovarian, omental, or pancreatic cysts. Solid masses include neuroblastoma, congenital mesoblastic nephroma, hepatoblastoma, and teratoma. A solid flank mass may be caused by renal vein thrombosis, which becomes clinically apparent with hematuria, hypertension, and thrombocytopenia. Renal vein thrombosis in infants is associated with polycythemia, dehydration, diabetic mothers, asphyxia, sepsis, and coagulopathies such as antithrombin III or protein C deficiency.

Abdominal distention at birth or shortly afterward suggests either obstruction or perforation of the gastrointestinal tract, often as a result of meconium ileus; later distention suggests lower bowel obstruction, sepsis, or peritonitis. A scaphoid abdomen in a newborn suggests diaphragmatic hernia. **Abdominal wall defects**

produce an omphalocele (Chapter 94) when they occur through the umbilicus and gastroschisis when they occur lateral to the midline. Omphaloceles are associated with other anomalies and syndromes such as Beckwith-Wiedemann, conjoined twins, trisomy 18, meningomyelocele, and imperforate anus. **Omphalitis** is an acute local inflammation of the periumbilical tissue that may extend to the abdominal wall, the peritoneum, the umbilical vein or portal vessels, or the liver and may result in later portal hypertension.

Genitals.

The **genitalia** and mammary glands normally respond to transplacentally acquired maternal hormones to produce enlargement and secretion of the breasts in both sexes and prominence of the female genitals, often with considerable nonpurulent discharge. These transitory manifestations require observation but no interference.

An imperforate hymen may result in **hydrometrocolpos** and a lower abdominal mass. A normal scrotum is relatively large; its size may be increased by the trauma of breech delivery or by a **transitory hydrocele,** which is distinguished from a hernia by palpation and transillumination. The testes should be in the scrotum or palpable in the canals. Black male infants usually have dark pigmentation of the scrotum before the rest of the skin assumes its permanent color.

The **prepuce** of a newborn infant is normally tight and adherent. Severe hypospadias or epispadias should always lead one to suspect either that abnormal sex chromosomes are present (Chapter 70) or that the infant is actually a masculinized female with an enlarged clitoris because this finding may be the first evidence of adrenogenital syndrome (Chapter 570). Erection of the penis is common and has no significance. Urine is usually passed during or immediately after birth; a period without voiding may normally follow. However, most void by 12?hr, and about 95% of preterm and term infants void within 24?hr.

Anus.

Some passage of meconium usually occurs within the first 12?hr after birth; 99% of term infants and 95% of premature infants pass meconium within 48?hr of birth. Imperforate anus is not always visible and may require evidence obtained by gentle insertion of the little finger or a rectal tube. Roentgenographic study is required. Passage of meconium does not rule out an imperforate anus if a rectal-vaginal fistula is present. The dimple or irregularity in skinfold often normally present in the sacrococcygeal midline may be mistaken for an actual or potential neurocutaneous sinus.

Extremities.

In examining the extremities, the effects of fetal posture (Chapter 662) should be noted so that their cause and usual transitory nature can be explained to the mother. Such explanations are particularly important after breech presentations. Observing the extremities in spontaneous or stimulated activity more commonly than by any other means arouses the suspicion of a fracture or nerve injury associated with delivery. The hands and feet should be examined for polydactyly, syndactyly, and abnormal dermatoglyphic patterns such as a simian crease.

The hips of all infants should be examined with specific maneuvers to rule out congenital dislocation (Chapter 668.1).

Neurologic Examination (see Chapters 6 and 584).

In utero neuromuscular diseases associated with limited fetal motion produce a constellation of signs and symptoms that are independent of the specific disease. Severe positional deformation and contractures produce arthrogryposis. Other manifestations of fetal neuromuscular disease include breech presentation, polyhydramnios, failure to breathe at birth, pulmonary hypoplasia, dislocated hips, undescended testes, thin ribs, and clubfoot.

83.3 Routine Delivery Room Care

Low-risk infants should be placed head downward immediately after delivery to clear the mouth, pharynx, and nose of fluid, mucus, blood, and amniotic debris by gravity; gentle suction

---

with a bulb syringe or soft rubber catheter may also be helpful in removing this material. Wiping the palate and pharynx with gauze may lead to abrasions and the development of thrush, pterygoid ulcers (Bednar aphthae), or rarely, tooth bud infection with maxillary osteomyelitis and retrobulbar abscess formation. The stomachs of infants delivered by cesarean section may contain more fluid than those of infants delivered vaginally. Their stomachs should be emptied by gastric tube to prevent aspiration of gastric contents. Most healthy infants who appear to be in satisfactory condition may be given directly to their mothers for immediate bonding and nursing. If respiratory distress is a concern, infants should be placed under a warmer with the head dependent.

The **Apgar score** is a practical method of systematically assessing newborn infants immediately after birth to help identify those requiring resuscitation and to predict survival in the neonatal period (Table 83–1). The 1-min Apgar score may signal the need for immediate resuscitation, and the 5-, 10-, 15-, and 20-min scores may indicate the probability of successfully resuscitating an infant. A low score may be due to a number of factors, including drugs given to the mother during labor and immaturity (Table 83–2). The Apgar score was not designed to predict neurologic outcome. Indeed, the score is normal in most patients in whom cerebral palsy subsequently develops, and the incidence of cerebral palsy is low (but higher than in infants with Apgar scores of 7–10) in infants with Apgar scores of 0–3 at 5?min. The Apgar score and umbilical artery blood pH both predict neonatal death. An Apgar score of 0–3 at 5?min is uncommon but is a better predictor of neonatal death (in both term and preterm infants) than an umbilical artery pH of 7.0 or less; combining these two variables increases the relative risk of neonatal mortality in term and preterm infants (Table 83–3).

Infants who fail to initiate respiration should receive prompt resuscitation and close observation (Chapter 89).

Maintenance of Body Heat.

Relative to body weight, the body surface of a newborn infant is approximately three times that of an adult, and in low-birthweight infants, the insulating layer of subcutaneous fat is thinner. The estimated rate of heat loss in a newborn is approximately four times that of an adult. Under the usual delivery room conditions (20–25℃), an infant's skin temperature falls approximately 0.3℃/min and deep body temperature decreases approximately 0.1℃/min during the period immediately after delivery; these rates generally result in a cumulative loss of 2–3℃ in deep body temperature (corresponding to a heat loss of approximately 200?kcal/kg). The heat loss occurs by *convection* of heat energy to the cooler surrounding air, by *conduction* of heat to the colder materials on which the infant is resting, by heat *radiation* from the infant to other nearby cooler solid objects, and by *evaporation* from moist skin and lungs (a function of alveolar ventilation).

Metabolic acidosis, hypoxemia, hypoglycemia, and increased renal excretion of water and solutes may develop in term

TABLE 83.3-1 -- **Apgar Evaluation of Newborn Infants**

Sign	0	1	2
Heart rate	Absent	Below 100	Over 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Response to catheter in nostril (tested after oropharynx is clear)	No response	Grimace	Cough or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

Sixty seconds after complete birth of the infant (disregarding the cord and placenta), the five objective signs above are evaluated, and each is given a score of 0, 1, or 2. A total score of 10 indicates an infant in the best possible condition.An infant with a score of 0–3 requires immediate resuscitation.

Modified from Apgar V: Res Anesth Analg 1953; 32:260

infants exposed to cold after birth because of their effort to compensate for heat loss. These conditions augment heat production by increasing the metabolic rate and oxygen consumption and by releasing norepinephrine, which results in nonshivering thermogenesis through oxidation of fat, particularly brown fat. In addition, muscular activity may increase. Hypoglycemic or hypoxic infants cannot increase their oxygen consumption when exposed to a cold environment, and their central temperature decreases. After labor and vaginal delivery, many newborn infants have mild to moderate metabolic acidosis, for which they may compensate by hyperventilating, a response that is more difficult for depressed infants and infants exposed to cold stress in the delivery room. Therefore, it is desirable to ensure that infants are dried and either wrapped in blankets or placed under a warmer while having skin-to-skin contact with the mother. Because carrying out resuscitative measures on a covered infant or one enclosed in an incubator is difficult, a radiant heat source should be used to heat the baby immediately after birth.

Antiseptic Skin and Cord Care.

Careful removal of blood from the skin shortly after birth may reduce the risk of infection with blood-borne agents. Once a healthy infant's temperature has stabilized, the entire skin and cord should be cleansed with warm water or a mild non-medicated soap solution and rinsed with water to reduce the incidence of skin and periumbilical colonization with pathogenic bacteria and subsequent infectious complications. To avoid heat loss, infants are then dried and wrapped in sterile blankets. To reduce colonization with *Staphylococcus aureus* and other pathogenic bacteria, the umbilical cord may be treated daily with bactericidal or antimicrobial agents such as triple dye or bacitracin. Alternatively, chlorhexidine washing or, on rare occasion during *S. aureus* epidemics, a single hexachlorophene bath may be used. Routine or repeated total body exposure to hexachlorophene may be neurotoxic, particularly in low-birthweight infants, and is thus contraindicated. Nursery personnel should use chlorhexidine or iodophor-containing antiseptic soaps for routine handwashing before caring for each infant. Rigidly enforcing hand-to-elbow washing for 2?min in the initial wash and 15–30?sec in the 2nd wash is essential for staff and visitors entering the nursery. Equally thorough washes between handling infants are also required.

Other Measures.

The eyes of all infants must be protected against gonococcal infection by instilling 1% *silver nitrate* drops, the best-proven therapy; erythromycin (0.5%) and tetracycline (1.0%) sterile ophthalmic ointments are alternative measures. Povidone-iodine (2.5% solution) may also be effective as a one-time prophylactic agent. This procedure may be delayed during the initial short-alert period after birth to promote bonding, but once applied, drops should not be rinsed out. Also see Chapters 177 and 208.3 .

Although hemorrhage in newborn infants can be due to factors other than *vitamin K deficiency*, an intramuscular injection of

TABLE 83.3-2 -- **Factors Affecting the Apgar Score**

False-Positive (No Fetal Acidosis or Hypoxia; Low Apgar)	False-Negative (Acidosis; Normal Apgar)

Immaturity	Maternal acidosis
Analgesics, narcotics, sedatives	High fetal catecholamine levels
Magnesium sulfate	Some full-term infants
Acute cerebral trauma	
Precipitous delivery	
Congenital myopathy	
Congenital neuropathy	
Spinal cord trauma	
Central nervous system anomaly	
Lung anomaly (diaphragmatic hernia)	
Airway obstruction (choanal atresia)	
Congenital pneumonia and sepsis	
Previous episodes of fetal asphyxia (recovered)	
Hemorrhage-hypovolemia	
Regardless of the etiology, a low Apgar score because of fetal asphyxia, mmaturity, central nervous system depression, or airway obstruction identifies an infant needing immediate resuscitation.	

1?mg of water-soluble vitamin K_1 (phytonadione) is recommended for all infants immediately after birth to prevent hemorrhagic disease of the newborn (see Chapter 92.4). Higher dose, repeated administration of oral vitamin K may also be useful, but this treatment is not yet established. Larger intravenous doses predispose to the development of hyperbilirubinemia and kernicterus and should be avoided. Administration of vitamin K to the mother during labor is not recommended because of unpredictable placental transfer.

Neonatal screening is available for various genetic, metabolic, hematologic, and endocrine diseases. All states have neonatal screening programs, although the specific tests required vary (Chapter 73). Laboratory tests performed on infant heel puncture blood samples include those for hypothyroidism, phenylketonuria, galactosemia, maple syrup urine disease, homocystinuria, biotinidase deficiency, adrenal hyperplasia, hemoglobinopathy, cystic fibrosis, tyrosinemia, and other organic acid defects or aminoacidopathies. To be effective in the timely identification and prompt management of treatable diseases, screening programs must include not only high-quality laboratory tests but also follow-up of infants with abnormal test results; education, counseling, and psychologic support for families; and prompt referral of the neonate for accurate diagnosis and therapy. Routine screening of the hematocrit or blood glucose is not necessary in the absence of risk factors. *Hearing impairment*, a serious morbidity that affects speech and language development, may be severe in 2/1,000 and overall affects 5/1,000 births. Universal screening of infants is recommended to ensure early detection of hearing loss and appropriate, timely intervention.

TABLE 83.3-3 -- **Incidence of Neonatal Death in 132,228 Singleton Infants Born at Term (37 wk of Gestation or Later) in Relation to Apgar Scores at 5?min of Age***

5-min No. of Apgar Score	Live Births	No. Neonatal Deaths Rate per 1,000 Births)	Relative Risk 95% CI)
0–3	86	21 (244)	1,460 (835–2,555)
4–6	561	5 (9)	53 (20–140)
7–10	131,581	22 (0.2)	1

**Infants with 5-min Apgar scores of 7–10 served as the reference group.*

83.4 Nursery Care

Non–high-risk healthy infants may be taken to the “regular” newborn nursery or be placed in the mother's room if the hospital has rooming-in.

The bassinet, preferably of clear plastic to allow for easy visibility and care, should be cleaned frequently. All professional care should be given in the bassinet, including the physical examination, clothing changes, temperature taking, skin cleansing, and other procedures that if performed elsewhere, would establish a common contact point and possibly provide a channel for cross infection. The clothing and bedding should be minimal, only that needed for an infant's comfort; the nursery temperature should be kept at approximately 24°C (75°F). The infant's temperature should be taken by axillary measurement. Although the interval between temperature taking depends on many circumstances, it need not be shorter than 4?hr during the 1st 2–3

days and 8?hr thereafter. Axillary temperatures of 36.4–37.0℃ (97.0–98.5℉) are within normal limits. Weighing at birth and daily thereafter is sufficient. Healthy infants should be placed supine to reduce the risk of sudden infant death syndrome.

Vernix is spontaneously shed within 2–3 days, much of it adhering to the clothing, which should be completely changed daily. The diaper should be checked before and after feeding and when the baby cries; it should be changed when wet or soiled. Meconium or feces should be cleansed from the buttocks with sterile cotton moistened with sterile water. The foreskin of a male infant should not be retracted. Circumcision is an elective procedure.

Early discharge (<48?hr) or very early discharge (<24?hr) may increase the risk of rehospitalization for hyperbilirubinemia, sepsis, failure to thrive, dehydration, and missed congenital anomalies. Early discharge requires careful ambulatory follow-up at home (visiting nurse) or in the office within 48?hr. Additional criteria for the early discharge of term neonates have been developed by the American Academy of Pediatrics and American College of Obstetrics and Gynecology (Box 83–2).

83.5 Parent-Infant Bonding (see also Chapter 9)

Normal infant development depends partly on a series of affectionate responses exchanged between a mother and her newborn infant that binds them together psychologically and physiologically. This bonding is facilitated and reinforced by the emotional support of a loving husband and family. The attachment process may be important in enabling some mothers to provide loving care during the neonatal period and subsequently during childhood. It is initiated before birth with the planning and confirmation of the pregnancy and with the growing acceptance of the fetus as an individual. After delivery and during the ensuing weeks, visual and physical contact between the mother and baby triggers various mutually rewarding and pleasurable interactions such as the mother touching the infant's extremities and face with her fingertips and encompassing and gently massaging the infant's trunk with her hands. Touching an infant's cheek elicits responsive turning toward the mother's face or toward the breast with nuzzling and licking of the nipple, a powerful stimulus for prolactin secretion. An infant's initial quiet alert state provides the opportunity for eye-to-eye contact, which is particularly important in stimulating the loving and possessive feelings of many parents for their babies. An infant's crying elicits the maternal response of touching the infant and speaking in a soft, soothing, higher-toned voice. Initial contact between the mother and infant should take place in the delivery room, and opportunities for extended intimate contact should be provided within the first hours after birth. Delayed or abnormal maternal-infant bonding, as occurs because of prematurity, infant or maternal illness, birth defects,

Box 83.5-2. Recommendations for Early Discharge from the Normal Newborn Nursery*

Uncomplicated antepartum, intrapartum, postpartum courses

Vaginal delivery

Singleton at 38–42 wk: appropriate for gestational age

Normal vital signs including respiratory rate <60 breaths/min; axillary temperature 36.1–37℃ (97.0–98.6℉) in open crib

Physical examination reveals no abnormalities requiring immediate attention

Urination; stool ×1

At least two uneventful, successful feedings

No excessive bleeding after (2?hr) circumcision

No jaundice within 24?hr of birth

Evidence of parental knowledge, ability, and confidence to care for the baby at home

- Feeding
- Cord, skin, genital care
- Recognition of illness (jaundice, poor feeding, lethargy, fever, etc.)
- Infant safety (car seat, supine sleep position, etc.)

Availability of family and physician support (physician follow-up)

Laboratory evaluation

*It is not likely that all these criteria will be met before 48?hr of age.

or family stress, may harm infant development and maternal caretaking ability. Hospital routines should be designed to encourage parent-infant contact.

Nurseries and Breast-Feeding.

See Chapter 41 for full discussions of breast-feeding and formula feeding. Many hospital practices contribute to difficulties in breast-feeding by enforcing 4-hr feeding schedules, limiting nursing time, using only one breast at a feeding, washing nipples with substances other than water, delaying the 1st feeding, providing formula supplements, and using heavy intrapartum sedation. The Baby-Friendly Hospital Initiative is a global effort (sponsored by the World Health Organization and the United Nations Children's Fund) to promote breast-feeding, which recommends 10 steps to successful breast-feeding (Box 83–3).

Hospital practices that encourage successful breast-feeding include immediate postpartum mother-infant contact with suckling, rooming-in, demand feeding, inclusion of fathers in prenatal breast-feeding education, and support from experienced women. Nursing at least 5?min at each breast is reasonable and allows a baby to obtain most of the available breast contents and provides effective stimulation for increasing the milk supply. Nursing episodes should then be extended according to the comfort and desire of the mother and infant. A confident and relaxed mother, supported by an encouraging home and hospital environment, is likely to nurse well.

Drugs and Breast-Feeding.

Maternal medications may affect the production and safety of breast milk (Table 83–4). Although most commonly used medications are safe, the safety of any drug to be used while a woman is breast-feeding must be confirmed before a new drug is initiated and/or breast-feeding is

Box 83.5-3. Ten Steps to Successful Breast-Feeding

Every facility providing maternity services and care for newborn infants should accomplish the following:

1. Have a written breast-feeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help mothers initiate breast-feeding within a half hour of birth.
5. Show mothers how to breast-feed and how to maintain lactation even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk unless *medically* indicated.
7. Practice rooming-in (allow mothers and infants to remain together) 24?hr a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or pacifiers

7. Practice rooming-in (allow mothers and infants to remain together) 24?hr a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or pacifiers (also called *dummies* or *soothers*) to breast-feeding infants.
10. Foster the establishment of breast-feeding support groups and refer mothers to them on discharge from the hospital or clinic.

From Protecting, Promoting and Supporting Breastfeeding: The Special Role of Maternity Services. A Joint WHO/UNICEF Statement Published by the World Health Organization, 1211 Geneva 27, Switzerland, 1989.

continued. Maternal sedatives may result in sedation of the infant. Maternal drugs that are weak acids, composed of large molecules, plasma bound, or poorly absorbed from the maternal or neonatal intestine are less likely to affect a neonate. When fresh breast milk is fed by tube or bottle, bacteriologic evaluation of stored milk should be performed within 24?hr.

TABLE 83.5-4 -- Drugs and Breast-Feeding

Contraindicated	Avoid or Give with Great Caution	Probably Safe but Give with Caution
Amphetamines	Amiodarone	Acetaminophen
Antineoplastic agents	Anthroquinones (laxatives)	Acyclovir
Bromocriptine	Aspirin (salicylates)	Aldomet
Chloramphenicol	Atropine	Anesthetics
Cimetidine	Birth control pills	Antibiotics (not tetracycline)

From Jones CA: Maternal transmission of infectious pathogens in breast milk. J Paediatr Child Health 2001; 37:576–82.

* *Provided that the mother and child are taking appropriate antibiotics.*

† *Provided that the mother is HIV-seronegative. Mothers should be counseled that breast milk transmission of hepatitis C virus has not been documented, but is theoretically possible.*

Medical contraindications to breast-feeding in the United States include infection with HIV, human T-cell leukemia virus types 1 and 2, cytomegalovirus (preterm infants), and hepatitis B virus (until an infant receives hepatitis B immune globulin and vaccine) (Table 83–5).

Chapter 84 - High-Risk Pregnancies

Barbara J. Stoll
Robert M. Kliegman

Pregnancies characterized by factors that increase the likelihood of abortion, fetal death, premature delivery, intrauterine growth restriction, fetal or neonatal disease, congenital malformations, mental retardation, or other handicaps are called high-risk pregnancies (Box 84–1 ; see also Chapter 85). Some factors, such as ingestion of a teratogenic drug in the 1st trimester, are causally related to the risk; others, such as hydramnios, are associations that alert a physician to determine the etiology and avoid the inherent risks associated with excessive amniotic fluid. Based on their history, 10–20% of pregnant patients can be identified as high risk; nearly half of all perinatal mortality and morbidity is associated with these pregnancies. Although assessing antepartum risk is important in reducing perinatal mortality and morbidity, some women become high risk only during labor and delivery; therefore, careful monitoring is critical throughout the intrapartum course.

Identifying high-risk pregnancies is important not only because it is the 1st step toward prevention but also because therapeutic steps may often be taken to reduce the risks to the fetus or neonate if the physician knows of the potential for difficulty.

Box 84-1. Factors Associated with High-Risk Pregnancy

ECONOMIC

- Poverty
- Unemployment
- Uninsured, underinsured health insurance
- Poor access to prenatal care

CULTURAL-BEHAVIORAL

- Low educational status
- Poor health care attitudes
- No care or inadequate prenatal care
- Cigarette, alcohol, drug abuse
- Age less than 20 or over 35 yr
- Unmarried
- Short interpregnancy interval
- Lack of support group (husband, family, religion)
- Stress (physical, psychologic)
- Black race

BIOLOGIC-GENETIC

- Previous low-birthweight or preterm infant
- Low weight for height
- Poor weight gain during pregnancy
- Short stature
- Low weight for height
- Poor weight gain during pregnancy
- Short stature
- Poor nutrition
- Inbreeding (autosomal recessive?)
- Intergenerational effects
- Low maternal birthweight
- Hereditary diseases (inborn error of metabolism)

REPRODUCTIVE

- Previous cesarean section
- Previous infertility
- Conception by reproductive technology
- Prolonged gestation
- Prolonged labor
- Previous infant with cerebral palsy, mental retardation, birth trauma, congenital anomalies
- Abnormal lie (breech)
- Multiple gestation
- Premature rupture of membranes
- Infections (systemic, amniotic, extra-amniotic, cervical)
- Preeclampsia or eclampsia
- Uterine bleeding (abruptio placentae, placenta previa)
- Parity (0 or more than 5)
- Uterine or cervical anomalies
- Fetal disease
- Abnormal fetal growth

Uterine or cervical anomalies

Fetal disease

Abnormal fetal growth

Idiopathic premature labor

Iatrogenic prematurity

High or low levels of maternal serum a-fetoprotein

MEDICAL

Diabetes mellitus

Hypertension

Congenital heart disease

Autoimmune disease

Sickle cell anemia

TORCH infection

Intercurrent surgery or trauma

Sexually transmitted diseases

Maternal hypercoagulable states

TORCH = toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.

Genetic Factors.

The occurrence of chromosomal abnormalities, congenital anomalies, inborn errors of metabolism, mental retardation, or any familial disease in blood relatives increases the risk of the same condition in the infant. Because many parents recognize only obvious clinical manifestations of genetically determined diseases, specific inquiry should be made about any disease affecting one or more blood relatives.

Maternal Factors.

The lowest neonatal mortality rate occurs in infants of mothers who receive adequate prenatal care and who are 20–30 yr of age. Both teenage pregnancies and those in women older than 40 yr, particularly primiparous women, carry an increased risk for intrauterine growth restriction, fetal distress, and intrauterine death. Advanced maternal age increases the risk of both chromosomal and non-chromosomal fetal malformations (Fig. 84–1).

Maternal illness (Table 84–1), multiple pregnancies, particularly those involving monochorionic twinning, infections (Table 84–2), and certain drugs (Chapter 85) increase the risk for the fetus. The use of assisted reproductive technology (in vitro fertilization, intracytoplasmic sperm injection) increases the risk of low birthweight and very low birthweight, as well as major birth defects and multiple-fetus pregnancies. Low birthweight, prematurity, and twinning in these infants also increases the risk of cerebral palsy.

Preterm birth is common in high-risk pregnancies (Chapter 86). Factors associated with prematurity are noted in Box 84–1 and include biologic markers such as cervical shortening, genital infection, fetal fibronectin in cervicovaginal secretions, and preterm premature rupture of membranes (PROM). The latter occurs in 1% of pregnancies but is noted in 30–40% of preterm deliveries, and it is a leading identifiable cause of prematurity. Premature delivery is often difficult to predict. Although women with preterm delivery have more spontaneous uterine contractions before the start of labor, this finding plus the length of the cervix and the presence of fetal fibronectin in cervical secretions has low sensitivity and poor positive predictive value for premature births.

Polyhydramnios and *oligohydramnios* indicate high-risk pregnancies. Although the turnover rate is rapid, during normal pregnancy the amniotic fluid volume gradually increases at a rate of less than 10?mL/day until about the 34th wk of pregnancy, after which it slowly diminishes. Volumes vary widely in normal pregnancy; term volume may be 500–2000?mL. A volume estimated at greater than 2,000?mL in the 3rd trimester constitutes polyhydramnios, and a volume estimated at less than 500?mL indicates oligohydramnios. Polyhydramnios complicates 1–3% and oligohydramnios complicates 1–5% of pregnancies. The ultrasonographic criteria for these diagnoses are based on the *amniotic fluid index*, which is determined by measuring the vertical diameter of amniotic fluid pockets in four quadrants; an index greater than 24?cm suggests polyhydramnios, whereas one less than 5?cm suggests oligohydramnios.

Acute polyhydramnios is rare and is usually associated with premature labor and delivery before 28 wk. Chronic polyhydramnios is diagnosed in the 3rd trimester by the discrepancy between uterine size and gestational age; it is occasionally not diagnosed until the patient has dysfunctional labor or an abnormally large amount of amniotic fluid is noted during delivery. Polyhydramnios is associated with premature labor, abruptio placentae, congenital anomalies, and fetal neuromuscular dysfunction or obstruction of the gastrointestinal tract that interferes with reabsorption of the amniotic fluid swallowed by the fetus (Box 84–2). Increased fetal urination or edema formation is also associated with excessive amniotic fluid volume. Ultrasound demonstrates the increased amniotic fluid surrounding the fetus and detects associated fetal anomalies, hydrops, pleural effusions, and ascites. In 60% of patients, no

Figure 84-1 Natural birth prevalence of Down syndrome according to maternal age. (From Wald NJ, Leck I: *Antenatal and Neonatal Screening*, 2nd ed. Oxford, Oxford University Press, 2000.)

TABLE 84-1 -- Maternal Disease Affecting the Fetus or Neonate

Disorder	Effects	Mechanism
Cholestasis	Preterm delivery	Unknown, possibly hepatitis E
Cyanotic heart disease	Intrauterine growth restriction	Low fetal oxygen delivery
Diabetes mellitus		
Mild	Large for gestational age, hypoglycemia	Fetal hyperglycemia—produces hyperinsulinemia; insulin promotes growth
Severe	Growth restriction	Vascular disease, placental insufficiency
Drug addiction	Intrauterine growth restriction, neonatal withdrawal	Direct drug effect plus poor diet
Endemic goiter	Hypothyroidism	Iodine deficiency
Graves disease	Transient neonatal thyrotoxicosis	Placental immunoglobin passage of thyroid-stimulating antibody
Herpes gestationalis	Bullous rash	Unknown
Hyperparathyroidism	Neonatal hypocalcemia	Maternal calcium crosses to fetus and suppresses fetal parathyroid gland
Hypertension	Intrauterine growth restriction, intrauterine fetal demise	Placental insufficiency, fetal hypoxia
Idiopathic thrombocytopenic purpura	Thrombocytopenia	Nonspecific maternal platelet antibodies cross placenta
Isoimmune neutropenia or thrombocytopenia	Neutropenia or thrombocytopenia	Specific antifetal neutrophil or platelet antibody crosses placenta after sensitization of mother
Malignant melanoma	Placental or fetal tumor	Metastasis
Myasthenia gravis	Transient neonatal myasthenia	Immunoglobin to acetylcholine receptor crosses placenta
Myotonic dystrophy	Neonatal myotonic dystrophy, congenital contractures, respiratory insufficiency	Genetic anticipation
Obesity	Macrosomia, hypoglycemia	Unknown
Phenylketonuria	Microcephaly, retardation	Elevated fetal phenylalanine levels
Preeclampsia, eclampsia	Intrauterine growth restriction, thrombocytopenia, neutropenia, fetal demise	Uteroplacental insufficiency, fetal hypoxia, vasoconstriction
Renal transplant	Intrauterine growth restriction	Uteroplacental insufficiency
Rhesus or other blood group sensitization	Fetal anemia, hypoalbuminemia, hydrops, neonatal jaundice	Antibody crosses placenta directed to fetal cells with antigen
Sickle cell anemia	Preterm birth, intrauterine growth restriction	Maternal sickling producing fetal hypoxia
Systemic lupus erythematosus	Congenital heart block, rash, anemia, thrombocytopenia, neutropenia	Antibody directed to fetal heart, red and white blood cells, and platelets

TABLE 84-2 -- Maternal Infections Affecting the Fetus or Newborn

Infection	Mode of Transmission	Outcome
Bacteria		
Group B streptococcus	Ascending cervical	Sepsis, pneumonia
Escherichia coli	Ascending cervical	Sepsis, pneumonia
Listeria monocytogenes	Transplacental	Sepsis, pneumonia
Ureaplasma urealyticum	Ascending cervical	Pneumonia, meningitis
Mycoplasma hominis	Ascending cervical	Pneumonia
Chlamydia trachomatis	Vaginal passage	Conjunctivitis, pneumonia

Syphilis	Transplacental, vaginal passage	Congenital syphilis
Borrelia burgdorferi	Transplacental	Prematurity, fetal demise
Neisseria gonorrhoeae	Vaginal passage	Ophthalmia (conjunctivitis), sepsis, meningitis
Mycobacterium tuberculosis	Transplacental	Prematurity, fetal demise, congenital tuberculosis
Granulocytic ehrlichiosis	Transplacental	Sepsis
Virus		
Rubella	Transplacental	Congenital rubella
Cytomegalovirus	Transplacental, breast milk (rare)	Congenital cytomegalovirus or asymptomatic
Human immunodeficiency virus	Transplacental, vaginal passage, breast milk	Congenital acquired immunodeficiency syndrome
Hepatitis B	Vaginal passage, transplacental, breast milk	Neonatal hepatitis, chronic HBsAg carrier
Hepatitis C	Transplacental	Uncommon but neonatal hepatitis, chronic carrier possible
Lymphocytic choriomeningitis	Transplacental	Fetal, neonatal death; hydrocephalus, chorioretinitis
Herpes simplex type 2	Transplacental	Congenital herpes simplex virus
	Vaginal passage, ascending	Neonatal encephalitis, disseminated viremia
Varicella-zoster	Transplacental, early	Congenital anomalies
	Transplacental, late	Neonatal varicella
Parvovirus	Transplacental	Fetal anemia, hydrops
Coxsackie B	Fecal-oral	Myocarditis, meningitis, hepatitis
Poliomyelitis	Transplacental	Congenital poliomyelitis
Epstein-Barr	Transplacental	Anomalies (?)
Rubeola	Transplacental	Abortion, fetal measles
West Nile	Transplacental	Chorioretinitis, focal cerebral necrosis
Parasites		
Toxoplasmosis	Transplacental	Congenital toxoplasmosis or asymptomatic
Malaria	Transplacental	Abortion, prematurty, intrauterine growth restriction
Trypanosomiasis	Transplacental	Congenital Chagas disease
Fungi		
Candida	Ascending, cervical	Sepsis, pneumonia, rash
Prion		
Creutzfeld-Jakob disease	Transplacental, colostrum	Hypothetical route, no long-term data

HBsAg = hepatitis B surface antigen.

cause is identified. Polyhydramnios may be managed by serial amniocentesis or by short-course maternal indomethacin if it is due to excessive fetal urination. Treatment is indicated for acute maternal respiratory distress and threatened preterm labor or to

Box 84-2. Conditions Associated with Disorders of Amniotic Fluid Volume

OLIGOHYDRAMNIOS	POLYHYDRAMNIOS
Intrauterine growth restriction Fetal anomalies Twin-twin transfusion (donor) Amniotic fluid leak	*Congenital anomalies:* Anencephaly, hydrocephaly, tracheoesophageal fistula, duodenal atresia, spina bifida, cleft lip or palate, cystic adenomatoid lung malformation, diaphragmatic hernia
Renal agenesis (Potter syndrome) Urethral atresia Prune-belly syndrome	*Syndromes:* Achondroplasia, Klippel-Feil, trisomy 18, trisomy 21, TORCH, hydrops fetalis, multiple congenital anomalad
Pulmonary hypoplasia Amnion nodosum Indomethacin Angiotensin-converting	*Other:* Diabetes mellitus, twin-twin transfusion (recipient), fetal anemia, fetal heart failure, polyuric renal disease, neuromuscular diseases,

Angiotensin-converting enzyme inhibitors	(recipient), fetal anemia, fetal heart failure, polyuric renal disease, neuromuscular diseases, nonimmune hydrops, chylothorax, teratoma
Intestinal pseudo-obstruction	
	Idiopathic

TORCH = toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.

provide time for the administration of corticosteroids to enhance fetal lung maturity.

Oligohydramnios is associated with congenital anomalies; intrauterine growth restriction; severe renal, bladder, or urethral anomalies; and drugs that interfere with fetal urination (see Box 84–2). The latter becomes most evident after 20 wk of gestation, when fetal urination is the major source of amniotic fluid. Rupture of the membranes must be ruled out when oligohydramnios is suspected, especially if a normal-sized bladder is seen on fetal ultrasonography. Oligohydramnios causes fetal compression abnormalities such as clubfoot, spadelike hands, and a flattened nasal bridge. The most serious complication of chronic oligohydramnios is pulmonary hypoplasia. The risk of umbilical cord compression during labor and delivery is increased in pregnancies complicated by oligohydramnios and may be alleviated by saline amnio-infusion. Ultrasonography may reveal small (1–2?cm) pockets of fluid in addition to the associated growth restriction or anomalies. Oligohydramnios in combination with an elevated a-fetoprotein level, uterine bleeding, or intrauterine growth restriction carries an increased risk of intrauterine fetal demise.

Antenatal screening can be used to detect a number of disorders, including Down syndrome and other chromosomal abnormalities, neural tube defects and other structural anomalies, Tay-Sachs disease and other metabolic genetic diseases, hemoglobinopathies and other blood disorders, and cystic fibrosis. Screening methods include maternal blood tests, fetal ultrasound, and diagnostic tests on cells or fluid obtained by amniocentesis

or chorionic villus sampling and by fetal blood or tissue sampling.

Second-trimester screening (15–18 wk) of maternal serum a-fetoprotein (MSAFP) levels is used to screen for open neural tube defects. About 90% of affected pregnancies can be detected by an elevated MSAFP level. Gastroschisis, omphalocele, congenital nephrosis, twins, and other abnormal conditions can also be identified. Low MSAFP is associated with incorrect gestational age estimates, trisomy 18 or 21, and intrauterine growth restriction.

Several effective screening strategies can be used to detect Down syndrome (Fig. 84–2), including a combination of maternal age, nuchal translucency on ultrasound, and a number of serum markers: a-fetoprotein, unconjugated estriol, total human chorionic gonadotropin (HCG), the free ß subunit of HCG, inhibin A, and pregnancy-associated plasma protein A. The most effective strategy, the integrated test, combines 1st-and 2nd-trimester screening and can identify 94% of affected pregnancies with a 5% false-positive rate or 85% with a 1% false-positive rate. Absence of the fetal nasal bone is also noted in trisomy 21. Chromosomal analysis of cells obtained by amniocentesis or chorionic villus biopsy makes the diagnosis.

Obstetric conditions are understandably important because fetuses weighing more than 2,500?g make up a very high proportion of total fetal deaths and neonatal mortality is greatest during the 1st 24?hr after delivery. A pregnancy should be considered high risk when the uterus is inappropriately large or small. A uterus large for the estimated stage of gestation suggests the presence of multiple fetuses, hydramnios, or an excessively large infant; an inappropriately small one suggests oligohydramnios or poor intrauterine growth. PROM earlier

Figure 84-2 Rates of detection of Down syndrome and false-positive rates for various screening tests. The triple test includes measurements of serum a-fetoprotein, unconjugated estriol, and human chorionic gonadotropin in the 2nd trimester. The quadruple test includes measurements of serum a-fetoprotein, unconjugated estriol, human chorionic gonadotropin, and inhibin A in the 2nd trimester. The combined test includes measurements of serum pregnancy-associated plasma protein A, free ß subunit of human gonadotropin, and nuchal translucency in the 1st trimester. The integrated test includes measurements of serum pregnancy-associated plasma protein A and nuchal translucency in the 1st trimester and measurements of serum a-fetoprotein, unconjugated estriol, human chorionic gonadotropin, and inhibin A in the 2nd trimester. (From Wald NJ, Watt HC, Hackshaw AK: Integrated screening for Down syndrome based on tests performed during the first and second trimester. *N Engl J Med* 1999; 341:461–7.)

than 24?hr before delivery carries a risk of fetal infection; it also increases the risk of premature birth. PROM at term usually results in the onset of labor within 48?hr but poses a risk of chorioamnionitis and umbilical cord compression. PROM before 37 wk has a longer latency until labor starts and has the added risks of cord prolapse, oligohydramnios, abruptio placentae, fetal malposition, and if present for more than 7 days, pulmonary hypoplasia, uterine-induced deformations, and extremity contractures. Prolonged and difficult labor increases the risk for mechanical and hypoxic damage. A tumultuous short labor with a precipitous delivery increases the risk of birth asphyxia and intracranial hemorrhage. Placental separation at any time before delivery and abnormal implantation or compression of the cord increase the possibility of brain damage from fetal anoxia; brown or muddy amniotic fluid suggests that meconium has been passed, possibly during an episode of fetal anoxia.

Although the safety of any type of delivery depends on the skill of the obstetrician, additional hazards accompany particular methods and result from the circumstances that dictated them. The risk of intracranial hemorrhage is greater in infants delivered by vacuum extraction, forceps, or cesarean section with labor than in those with unassisted spontaneous vaginal deliveries. Neonatal deaths after deliveries by mid and high forceps, breech extraction, and version are likely to be related to traumatic intracranial injury.

Infants born by *cesarean section* present problems possibly related to the unfavorable obstetric circumstance that necessitated the operation or to prolonged maternal anesthesia. In normal term pregnancies without any indication of fetal

distress, delivery through the abdomen carries a greater risk than

delivery through the birth canal does. However, controversy exists regarding the safest type of delivery for a non-distressed, viable immature fetus, especially in a breech presentation; cesarean section may involve less risk than the "stress" of labor and the potentially anoxic effects of uterine contractions during vaginal delivery. Term breech positions (?3–4% of term births) that do not become vertex after external cephalic version will also benefit from cesarean section. A small percentage of mature infants delivered by cesarean section have some degree of respiratory difficulty for 1–2 days. Although transient tachypnea is the most frequently associated problem, hyaline membrane disease may develop, particularly in infants born to women not in labor, those with uncertain dates or pulmonary maturity, and those born to diabetic mothers or after asphyxia. A trial of labor after a previous cesarean section also increases the risk of perinatal demise.

Anesthesia and analgesia affect the fetus as well as the mother; mild maternal hypoxemia secondary to hypoventilation or hypotension resulting from epidural anesthesia may result in severe fetal hypoxia and shock. Skilled use of medication avoids severe fetal narcosis while securing the benefits of gentle and unhurried delivery. Even skilled administration may result in a mildly depressed infant whose crying and breathing may be delayed 1–2?min and who may be somewhat inactive for several hours. When anesthesia and analgesia are carelessly used or when their milder effects are added to already unfavorable fetal circumstances such as prematurity, anoxia, or trauma, the result may be catastrophic.

Chapter 85 - The Fetus

Barbara J. Stoll
Robert M. Kliegman

Genetic and environmental influences may affect an embryo and fetus at any time during development; the fetal genome itself has a significant role in development and fetal survival, as does the uterine environment.

The major emphasis in fetal medicine involves (1) assessment of fetal growth and maturity, (2) evaluation of fetal well-being or distress, (3) assessment of the effects of maternal disease on the fetus, (4) evaluation of the effects of drugs administered to the mother on the fetus, and (5) identification and treatment of fetal disease or anomalies. Increasing knowledge of fetal physiology has paved the way for effective fetal therapy, intervention during fetal distress, and improved adaptation of a newborn infant, particularly a premature one, to extrauterine life. Some aspects of human fetal growth and development are summarized in Chapter 8 .

85.1 Fetal Growth and Maturity

Ultrasonography of the fetus, a common obstetric procedure, is both safe and accurate. Indications for antenatal ultrasonography include estimation of gestational age (unknown dates, discrepancy between uterine size and dates or suspected growth retardation, multiple gestation, and abnormalities in amniotic fluid volume), location of the placenta, determination of the number and position of fetuses, and identification of congenital anomalies.

Fetal growth can be assessed by ultrasonography as early as 6–8 wk. The most accurate assessment of gestational age is by 1st-trimester ultrasound measurement of crown-rump length. The biparietal diameter is used to assess gestational age beginning in the 2nd trimester. Through 34 wk the biparietal diameter accurately estimates gestation to within ±10 days. Later in gestation, accuracy falls to ±3 wk. Methods used to assess gestational age at term include measurement of abdominal circumference and femoral length. An estimate of gestational age by dating of the last menstrual period should also be obtained. If a single ultrasound examination is performed, the most information can be obtained with a scan at 18 to 20 wk, when both gestational age and fetal anatomy can be evaluated. Serial scans may be useful in assessing fetal growth. Two patterns of fetal growth restriction have been identified: continuous fetal growth 2 SD below the mean for gestational age and a normal fetal growth curve that abruptly slows or flattens later in gestation (Fig. 85–1).

Fetal maturity is usually assessed by accurate ultrasonographic dating of gestational age, but it may also be estimated by determining the surfactant content of amniotic fluid (Chapters 85.5 and 90). Determination of the extent of calcification by ultrasound (placental maturity index), detection of the 1st audible fetal heart tones (16–18 wk), and observation of the initial fetal movements (18–20 wk) may also aid in evaluating the maturity of a fetus.

85.2 Fetal Distress

Fetal compromise may occur during the antepartum or intrapartum periods but may be asymptomatic in the antenatal period. Antepartum fetal surveillance is warranted for women at increased risk for fetal distress, including those with a history of stillbirth, intrauterine growth restriction (IUGR), oligohydramnios or polyhydramnios, multiple gestation, rhesus sensitization, hypertensive disorders, diabetes mellitus or other

Figure 85.2-1 *A*, Example of a “low-profile” growth retardation pattern in an uneventful pregnancy and labor. The baby cried at 1?min and hypoglycemia did not develop. Birthweight was below the 5th percentile for gestational age. *B*, Example of a “late flattening” growth retardation pattern. The mother had a typical history of preeclampsia, and the infant had intrapartum fetal distress, a low Apgar score, and postnatal hypoglycemia. Birthweight was below the 5th percentile for gestational age. (From Campbell S: *Clin Obstet Gyneco*l 1974;1:41.)

chronic maternal disease, decreased fetal movement, and post-term pregnancy. The predominant cause of antepartum fetal distress is uteroplacental insufficiency. Fetal distress may be manifested as IUGR, fetal hypoxia, increased vascular resistance in fetal blood vessels (Figs. 85–2 and 85–3), and when severe, mixed respiratory and metabolic (lactic) acidosis. The goals of antepartum fetal surveillance are to prevent intrauterine fetal demise, prevent hypoxic brain injury, and prolong gestation in women at risk for preterm delivery when such prolongation is safe or deliver a fetus when it is in jeopardy. The most commonly used tests are the *nonstress test* (NST), the *contraction stress test* (CST), and the *biophysical profile* (BPP). Methods for assessing fetal well-being are listed in Table 85–1 .

The NST monitors the presence of fetal heart rate accelerations that follow fetal movement. A reactive (normal) NST result demonstrates two fetal heart rate accelerations of at least 15 beats/min lasting 15?sec. A nonreactive NST result suggests fetal compromise and requires further assessment with a CST or the BPP. A CST observes the fetal heart rate response to spontaneous, nipple-, or oxytocin-stimulated uterine contractions. Fetal compromise is suggested when three contractions in 10?min are followed by late decelerations. A CST is contraindicated in women with preterm premature rupture of membranes or a previous uterine scar from a classic cesarean section and in those with multiple gestations, an incompetent cervix, or placenta previa. The goals of fetal monitoring are to prevent intrauterine fetal demise and hypoxic brain injury. Although the CST and NST have

low false-negative rates, both have high false-positive rates. The BPP assesses fetal breathing, body movement, tone, heart rate, and amniotic fluid volume, and it is used to improve the accurate and safe identification of fetal compromise (Table 85–2). A score of 2 is given for each observation present. A total score of 8–10 is reassuring; a score of 6 is equivocal, and retesting should be done in 12–24?hr; and a score of 4 or less warrants immediate evaluation and possible delivery. Signs of compromise seen on Doppler ultrasonography include a reduced, absent, or reversed diastolic waveform velocity in the fetal aorta or umbilical artery (see Fig. 85–3 and Table 85–1). High-risk fetuses often have combinations of abnormalities, such as oligohydramnios, reversed diastolic Doppler umbilical artery blood flow velocity, and a low BPP.

Fetal distress during labor may be detected by monitoring the fetal heart rate, uterine pressure, and fetal scalp blood pH (Fig. 85–4).

Continuous fetal heart rate monitoring detects abnormal cardiac patterns by instruments that compute the beat-to-beat fetal heart rate from a fetal electrocardiographic signal. Signals are derived from an electrode attached to the fetal presenting part, from an ultrasonic transducer placed on the maternal abdominal wall to detect continuous ultrasonic waves reflected from the contractions of the heart, or from a phonotransducer placed on the mother's abdomen. Uterine contractions are simultaneously recorded from an amniotic fluid catheter and pressure transducer or from a tocotransducer applied to the maternal abdominal wall overlying the uterus.

Fetal heart rate patterns show various characteristics, some of which suggest fetal distress. The baseline fetal heart rate is the average rate between uterine contractions, which gradually decreases from about 155 beats/min in early pregnancy to about 135 beats/min at term; the normal range at term is 120–160 beats/min. **Tachycardia** (>160 beats/min) is associated with early fetal hypoxia, maternal fever, maternal hyperthyroidism, maternal ß-sympathomimetic or atropine therapy, fetal anemia, infection, and some fetal arrhythmias. The latter do not generally occur with congenital heart disease and may resolve spontaneously at birth. **Fetal bradycardia** (<120 beats/min) occurs with fetal hypoxia, placental transfer of local anesthetic agents and ß-adrenergic blocking agents, and occasionally, heart block with or without congenital heart disease.

Normally, the baseline fetal heart rate is variable, with long-term changes of 3–6 cycles/min, as well as short-term beat-to-beat variation. This variability may be decreased or lost with

Figure 85.2-2 Normal Doppler velocimetry in sequential studies of fetal umbilical artery flow velocity waveforms from one normal pregnancy. Note the systolic peak flow with lower, but constant flow during diastole. The systolic:diastolic ratio can be determined and, in normal pregnancies, is less than 3 after the 30th wk of gestation. The numbers indicate the week of gestation. (From Trudinger B: Doppler ultrasound assessment of blood flow. In Creasy RK, Resnik R [editors]: *Maternal-Fetal Medicine: Principles and Practice*, 3rd ed. Philadelphia, WB Saunders, 1994.)

fetal hypoxemia or the placental transfer of drugs such as atropine, diazepam, promethazine, magnesium sulfate, and most sedative and narcotic agents. Prematurity, the sleep state, and fetal tachycardia may also diminish beat-to-beat variability.

Periodic accelerations or decelerations of the fetal heart rate in response to uterine contractions may also be monitored (see Fig. 85–4). **Early deceleration** (type I), associated with head compression, is a repetitive pattern of slowing that is synchronous with and proportional to the amplitude of the uterine contraction. **Variable deceleration** (associated with cord compression) is characterized by variable shape, abrupt onset and occurrence with consecutive contractions, and return to baseline at or after the conclusion of the contraction. **Late deceleration** (type II), associated with fetal hypoxemia, occurs repetitively after a uterine contraction is well established, is proportional to its amplitude, and persists into the interval following contractions. The late deceleration pattern is usually associated with maternal hypotension or excessive uterine activity, but it may be a response to any maternal, placental, umbilical cord, or fetal factor that limits effective oxygenation

Figure 85.2-3 Abnormal Doppler velocimetry. On an umbilical artery Doppler flow velocity waveform, the umbilical placental impedance is so high that the diastolic component shows flow in a reverse direction. This finding is an indication of severe intrauterine hypoxia and intrauterine growth restriction. (From Trudinger B: Doppler ultrasound assessment of blood flow. In Creasy RK, Resnik R [editors]: *Maternal-Fetal Medicine: Principles and Practice*, 3rd ed. Philadelphia, WB Saunders, 1994.)

of the fetus. Reflex late decelerations with normal beat-to-beat variability are associated with chronic compensated fetal hypoxia, and they occur during uterine contractions that temporarily impede oxygen transport to the heart. Nonreflex late decelerations are more ominous and indicate severe hypoxic depression of myocardial function. The latter, together with decreased beat-to-beat variability or spontaneous decelerations in the absence of uterine contractions, either warrants further assessment by fetal blood sampling or is an indication for delivery.

Fetal scalp blood sampling during labor through a slightly dilated cervix may aid in confirming fetal distress suspected on the basis of variations in fetal heart rate or the presence of meconium in amniotic fluid. The proper use of this technique may result in earlier delivery of depressed infants, who thus have a better chance of successful resuscitation, increased survival, and less morbidity. Alternatively, when continuous fetal heart rate monitoring or general clinical evaluation suggests that a fetus is at risk, a normal fetal scalp blood sample may help avert obstetric intervention.

Fetal scalp blood pH in normal labor decreases from about 7.33 early in labor to approximately 7.25 at the time of vaginal delivery; the base deficit is about 4–6?mEq/L. Changes in the buffer base may be particularly helpful in assessing fetal status because they correspond to the accumulation of fetal lactic acid. A pH less than 7.25 strongly suggests fetal distress, and a pH less than 7.20 is an indication for further assessment and intervention. Determination of the lactate concentration in fetal scalp blood is another tool for monitoring the condition of the fetus.

Complications of fetal scalp sampling and internal monitoring devices are relatively uncommon but include bleeding (usually because of an underlying coagulation defect), puncture of the fontanel, and scalp abscesses with or without adjacent

osteomyelitis. Abscesses may be due to *Staphylococcus aureus* or gram-negative rods; more often they are sterile.

Umbilical cord blood samples obtained at the time of delivery are useful to document fetal acid-base status. Although the exact cord blood pH value that defines significant fetal acidemia is unknown, an umbilical artery pH less than 7.0 has been associated with greater need for resuscitation and a higher incidence of respiratory, gastrointestinal, cardiovascular, and neurologic complications. However, when a low pH is detected, many newborn infants will be neurologically normal.

TABLE 85.2-1 -- Fetal Diagnosis and Assessment

Method	Comment and Indications
Imaging	
Ultrasound (real-time)	Biometry (growth), anomaly (morphology) detection. Biophysical profile. Amniotic fluid volume, hydrops. Determine gestational age and IUGR
Ultrasound (Doppler)	Velocimetry (blood flow velocity). Detection of increased vascular resistance secondary to fetal hypoxia, IUGR
Embryoscopy	Early diagnosis of limb anomaly
Fetoscopy	Detection of facial, limb, cutaneous anomalies
MRI	Best to define lesions before EXIT procedure
Fluid Analysis	
Amniocentesis	Fetal maturity (L:S ratio), karyotype (cytogenetics), biochemical enzyme analysis, molecular genetic DNA diagnosis, bilirubin, or a-fetoprotein determination. Bacterial culture, pathogen antigen or genome detection
Fetal urine	Prognosis of obstructive uropathy?
Cordocentesis (Percutaneous Umbilical Blood Sampling)	Detection of blood type, anemia, hemoglobinopathies, thrombocytopenia, acidosis, hypoxia, polycythemia, IgM antibody response to infection. Rapid karyotyping and molecular DNA genetic diagnosis. Fetal therapy (see Table 85–5)
Fetal Tissue Analysis	
Chorionic villus biopsy	Karyotype, molecular DNA genetic analysis, enzyme assays
Skin biopsy	Hereditary skin disease*
Liver biopsy	Enzyme assay*
Circulating fetal cells in maternal blood	Molecular DNA genetic analysis
Maternal Serum a-Fetoprotein	
Elevated	Twins, neural tube defects (anencephaly, spina bifida), intestinal atresia, hepatitis, nephrosis, fetal demise, incorrect gestational age
Reduced	Trisomies, aneuploidy
Maternal Cervix	
Fetal fibronectin	Indicates risk of preterm birth
Bacterial culture	Identifies risk of fetal infection (group B streptococcus, ***Neisseria gonorrhoeae***)
Fluid	Determination of premature rupture of membranes
Antepartum Biophysical Monitoring	
Nonstress test	Fetal distress; hypoxia
Contraction stress test	Fetal distress; hypoxia
Biophysical profile	Fetal distress; hypoxia
Intrapartum Fetal Heart Rate Monitoring	See Fig. 85–4

IUGR = intrauterine growth restriction; EXIT = ex utero intrapartum treatment (endoscopy, drain placement, surgery); L:S = lecithin:sphingomyelin ratio.

* *DNA genetic analysis on chorionic villus samples, amniocytes from amniocentesis, or fetal cells recovered from the maternal circulation may obviate the need for direct fetal tissue biopsy if the gene or genetic marker is available (e.g., the gene for Duchenne's muscular dystrophy).*

85.3 Maternal Disease and the Fetus

Infectious Diseases (see Table 84–2).

Almost any maternal infection with severe systemic manifestations may result in miscarriage, stillbirth, or premature labor. Whether these results are due to infection of the fetus or are secondary to stress is not always clear. Maternal hyperthermia during infections may be associated with an increased incidence of congenital anomalies. Regardless of the severity of the maternal infection, certain agents frequently infect a fetus and result in serious sequelae. Such fetuses are often small for gestational age. Some infections, such as rubella, may also produce congenital malformations if they occur during the period of organogenesis. Intrauterine infection/chorioamnionitis may

TABLE 85.3-2 -- Biophysical Profile Scoring: Technique and Interpretation

Biophysical Variable	Normal Score (2)	Abnormal Score (0)

Fetal breathing movements	At least 1 episode of FBM of at least 30?sec duration in 30?min observation	Absent FBM or no episode of =30?sec in 30?min
Gross body movement	At least 3 discrete body/limb movements in 30?min (episodes of active continuous movement considered a single movement)	2 or fewer episodes of body/limb movements in 30?min
Fetal tone	At least 1 episode of active extension with return to flexion of fetal limb(s) or trunk. Opening and closing of hand considered normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absent fetal movement with fetal hand held in complete or partial deflection
Reactive FHR	At least 2 episodes of FHR acceleration of = beats/min and at least 15?sec duration associated with fetal movement in 30?min	Less than 2 episodes of acceleration of FHR or acceleration of <15 beats/min in 30?min
Qualitative AFV*	At least 1 pocket of AF that measures at least 2?cm in 2 perpendicular planes	Either no AF pockets or a pocket <2?cm in 2 perpendicular planes

FBM = fetal breathing movement; FHR = fetal heart rate; AFV = amniotic fluid volume; AF = amniotic fluid.

From Creasy RK, Resnik R (editors): Maternal-Fetal Medicine: Principles and Practice, 3rd ed. Philadelphia, WB Saunders, 1994.

* *Modification of the criteria for reduced amniotic fluid from less than 1?cm to less than 2?cm would seem reasonable. Ultrasound is used for biophysical assessment of the fetus.*

be an important risk factor for cerebral white matter injury and subsequent cerebral palsy.

Noninfectious Diseases (see Table 84–1).

Maternal diabetes may result in organomegaly, hypertrophy and hyperplasia of the ß cells of the fetal pancreas, and metabolic derangements in the neonate (Chapter 96.1). A high incidence of intrauterine death occurs after the 36th wk of gestation in unmonitored and poorly controlled mothers. Moreover, maternal diabetes is a risk factor for cardiovascular and other malformations. *Eclampsia-preeclampsia* of pregnancy, chronic hypertension, and chronic renal disease result in small fetal size for gestational age, prematurity, and intrauterine death, all probably caused by diminished uteroplacental perfusion. Uncontrolled maternal *hypothyroidism*

Figure 85.3-4 Patterns of periodic fetal heart rate (FHR) deceleration. The tracing in *A* shows early deceleration occurring during the peak of uterine contractions as a result of pressure on the fetal head. *B*, Late deceleration caused by uteroplacental insufficiency. *C*, Variable deceleration as a result of umbilical cord compression. Arrows denote the time relationship between the onset of FHR changes and uterine contractions. (From Hon EH: *An Atlas of Fetal Heart Rate Patterns*. New Haven, CT, Harty Press, 1968.)

or *hyperthyroidism* is responsible for relative infertility, a tendency to abort, premature labor, and fetal death. Hypothyroidism in pregnant women (even if mild or asymptomatic) can adversely affect neurodevelopment of the child. Maternal *immunologic diseases* such as idiopathic thrombocytopenic purpura, systemic lupus erythematosus, myasthenia gravis, and Graves disease, all of which are mediated by IgG autoantibodies that can cross the placenta, frequently result in transient illness in the newborn. Untreated maternal *phenylketonuria* results in miscarriage, congenital cardiac malformations, and injury to the brain of a non-phenylketonuric heterozygotic fetus.

85.4 Maternal Medication and Toxin Exposure and the Fetus

Consumption of medications in pregnancy is frequent; surveys indicate that 90% of pregnant patients have taken at least one drug. The average mother has taken 4 drugs other than vitamins or iron during pregnancy; 4% have taken 10 drugs or more. Moreover, many women are exposed to potential reproductive toxins, such as occupational, environmental, or household chemicals, including solvents, pesticides, and hair products. The effects of drugs taken by the mother vary considerably, especially in relation to the time in pregnancy when they are taken and perhaps the fetal genotype for drug-metabolizing enzymes. Miscarriage or congenital malformations result from the maternal ingestion of teratogenic drugs during the period of organogenesis. Maternal medications taken later, particularly during the last few weeks of gestation or during labor, tend to affect the function of specific organs or enzyme systems, and they adversely affect the neonate rather than the fetus (Table 85–3 and Box 85–1).

The effects of drugs may be evident immediately in the delivery room or later in the neonatal period, or they may be delayed even longer. The administration of diethylstilbestrol during pregnancy has resulted in vaginal adenosis and vaginal adenocarcinoma in older female children. In addition to in utero carcinogenesis, various reproductive problems have been reported in these women, including cervical anomalies and premature births, ectopic pregnancies, and spontaneous pregnancy loss.

TABLE 85.4-3 -- **Agents Acting on Pregnant Women That May Adversely Affect the Structure or Function of the Fetus and Newborn**

Drug	Effect on Fetus

Accutane (isotretinoin)	Facial-ear anomalies, heart disease
Alcohol	Congenital cardiac, CNS, limb anomalies; IUGR; developmental delay; attention deficits; autism
Aminopterin	Abortion, malformations
Amphetamines	Congenital heart disease, IUGR, withdrawal
Azathioprine	Abortion
Busulfan (Myleran)	Stunted growth; corneal opacities; cleft palate; hypoplasia of ovaries, thyroid, and parathyroids
Carbamazepine	Spina bifida, possible neurodevelopment delay
Carbon monoxide	Cerebral atrophy, microcephaly, seizures
Chloroquine	Deafness
Chorionic villus sampling	Probably no effect, possibly limb reduction
Cigarette smoking	Low birthweight for gestational age
Cocaine/crack	Microcephaly, LBW, IUGR, behavioral disturbances
Cyclophosphamide	Multiple malformations
Danazol	Virilization
17a-Ethinyl testosterone (Progestoral)	Masculinization of female fetus
Hyperthermia	Spina bifida
Lithium	Ebstein's anomaly, macrosomia
6-Mercaptopurine	Abortion
Methyl mercury	Minamata disease, microcephaly, deafness, blindness, mental retardation
Methyltestoserone	Masculinization of female fetus
Misoprostol	Arthrogryposis, cranial neuropathies (Möbius syndrome), equinovarus
Norethindrone	Masculinization of female fetus
Penicillamine	Cutis laxa syndrome
Phenytoin	Congenital anomalies, IUGR, neuroblastoma, bleeding (vitamin K deficiency)
Polychlorinated biphenyls	Skin discoloration—thickening, desquamation, LBW, acne, developmental delay
Prednisone	Oral clefts
Progesterone	Masculinization of female fetus
Quinine	Abortion, thrombocytopenia, deafness
Stilbestrol (diethylstilbestrol [DES])	Vaginal adenocarcinoma in adolescence
Streptomycin	Deafness
Tetracycline	Retarded skeletal growth, pigmentation of teeth, hypoplasia of enamel, cataract, limb malformations
Thalidomide	Phocomelia, deafness, other malformations
Toluene (solvent abuse)	Craniofacial abnormalities, prematurity, withdrawal symptoms, hypertonia
Trimethadione and paramethadione	Abortion, multiple malformations, mental retardation
Valproate	Spina bifida, impaired neurologic function
Vitamin D	Supravalvular aortic stenosis, hypercalcemia
Warfarin (Coumadin)	Fetal bleeding and death, hypoplastic nasal structures

CNS = central nervous system; IUGR = intrauterine growth restriction; LBW = low birthweight.

Box 85.4-1. Agents Acting on Pregnant Women That May Adversely Affect the Newborn Infant

Acebutolol–IUGR, hypotension, bradycardia

Acetazolamide–metabolic acidosis

Amiodarone–bradycardia, hypothyroidism

Anesthetic agents (volatile)–CNS depression

Adrenal corticosteroids–adrenocortical failure (rare)

Ammonium chloride–acidosis (clinically inapparent)

Aspirin–neonatal bleeding, prolonged gestation

Atenolol–IUGR, hypoglycemia

Blue cohosh herbal tea–neonatal heart failure

Bromides–rash, CNS depression, IUGR

Captopril, enalapril–transient anuric renal failure, oligohydramnios

Caudal-paracervical anesthesia with mepivacaine (accidental introduction of anesthetic into scalp of baby)–bradypnea, apnea, bradycardia, convulsions

Cholinergic agents (edrophonium, pyridostigmine)–transient muscle weakness

CNS depressants (narcotics, barbiturates, benzodiazepams) during labor–CNS depression, hypotonia

anesthetic into scalp of baby)–bradypnea, apnea, bradycardia, convulsions

Cholinergic agents (edrophonium, pyridostigmine)–transient muscle weakness

CNS depressants (narcotics, barbiturates, benzodiazepams) during labor–CNS depression, hypotonia

Cephalothin–positive direct Coombs test reaction

Dexamethasone–periventricular leukomalacia

Fluoxetine–possible transient neonatal withdrawal, hypertonicity, minor anomalies

Haloperidol–withdrawal

Hexamethonium bromide–paralytic ileus

Ibuprofen–oligohydramnios, pulmonary hypertension

Imipramine–withdrawal

Indomethacin–oliguria, oligohydramnios, intestinal perforation, pulmonary hypertension

Intravenous fluids during labor (e.g., salt-free solutions)–electrolyte disturbances, hyponatremia, hypoglycemia

Iodide (radioactive)–goiter

Iodides–goiter

Isoxsuprine–ileus, hypocalcemia, hypoglycemia, hypotension

Lead–reduced intellectual function

Magnesium sulfate–respiratory depression, meconium plug, hypotonia

Methimazole–goiter, hypothyroidism

Morphine and its derivatives (addiction)–withdrawal symptoms (poor feeding, vomiting, diarrhea, restlessness, yawning and stretching, dyspnea and cyanosis, fever and sweating, pallor, tremors, convulsions)

Naphthalene–hemolytic anemia (in G6PD-deficient infants)

Nitrofurantoin–hemolytic anemia (in G6PD-deficient infants)

Oxytocin–hyperbilirubinemia, hyponatremia

Phenobarbital–bleeding diathesis (vitamin K deficiency), possible long-term reduction in IQ, sedation

Primaquine–hemolytic anemia (in G6PD-deficient infants)

Propranolol–hypoglycemia, bradycardia, apnea

Propylthiouracil–goiter, hypothyroidism

Pyridoxine–seizures

Propranolol–hypoglycemia, bradycardia, apnea

Propylthiouracil–goiter, hypothyroidism

Pyridoxine–seizures

Reserpine–drowsiness, nasal congestion, poor temperature stability

Sulfonamides–interfere with protein binding of bilirubin; kernicterus at low levels of serum bilirubin, hemolysis with G6PD deficiency

Sulfonylurea–refractory hypoglycemia

Sympathomimetic (tocolytic ß-agonist) agents–tachycardia

Thiazides–neonatal thrombocytopenia (rare)

IUGR = intrauterine growth restriction; CNS = central nervous system; G6PD = glucose-6-phosphate dehydrogenase.

Evidence has confirmed an interaction between genetic factors and susceptibility to certain drugs or environmental toxins. For example, phenytoin teratogenesis may be mediated by genetic differences in the enzymatic production of epoxide metabolites, and specific genes may influence the adverse effects of benzene exposure during pregnancy. Polymorphisms of genes encoding enzymes that metabolize the polycyclic aromatic hydrocarbons in cigarette smoke influence the growth-restricting effects of smoking on the fetus.

In view of the limits of current knowledge on the fetal effects of maternal medication, no drugs should be prescribed during pregnancy without weighing maternal need against the risk of fetal damage. All women should be specifically counseled to abstain from the use of alcohol, tobacco, and illicit drugs during pregnancy.

85.5 Teratogens

When an infant or child is malformed or mentally retarded, the parents often wrongly blame themselves and attribute the child's problems to events that occurred during pregnancy. Because infections occur and several drugs are often taken during many pregnancies, the pediatrician must evaluate the presumed viral infections and the drugs ingested to help parents understand their child's birth defect. The causes of approximately 40% of congenital malformations are unknown. Although only a relatively few agents are recognized to be teratogenic in humans (see Tables 84–1 , 84–2 , 85–3 , and Box 85–1), new agents continue to be identified. Overall, only 10% of anomalies are due to recognizable teratogens. The time of exposure is usually at less than 60 days' gestation during organogenesis. Specific agents produce predictable lesions. Some agents have a dose or threshold effect; below the threshold, no alterations in growth, function, or structure occur. The agent's effects may be species specific. Genetic variables such as the presence of specific enzymes may metabolize a benign agent into a more toxic-teratogenic form (phenytoin conversion to its epoxide). In many circumstances, the same agent and dose may

not consistently produce the lesion.

Reduced enzyme activity of the folate methylation pathway, particularly the formation of 5-methyltetrahydrofolate, may be responsible for neural tube or other birth defects. The common thermolabile mutation of 5,10-methylene tetrahydrofolate reductase may be one of the enzymes responsible. Folate supplementation for all pregnant women (by direct fortification of cereal grains, mandatory in the United States) during organogenesis may overcome this genetic enzyme defect, thus reducing the incidence of neural tube and perhaps other birth defects.

Mechanisms of teratogenesis include cell death without reparative regeneration; mitotic delay; delayed differentiation; physical or vascular constraining events; reduced histogenesis secondary to cell depletion, necrosis, calcification, or scarring; inhibited cellular migration; and inflammation. Many mechanisms occur secondary to chromosomal or DNA damage and poor molecular repair.

The Food and Drug Administration classifies drugs into five pregnancy risk categories. *Category A* suggests no risk based on evidence from controlled human trials. *Category B* suggests either no risk shown in animal studies but no adequate studies in humans or some risk in animal studies that are not confirmed by human studies. *Category C* is either definite risk shown in animal studies but no adequate human studies or no available data for animals or humans. *Category D* includes drugs with some risk but with a benefit that may exceed that risk for the treated life-threatening condition, such as streptomycin for tuberculosis. *Category X* is for drugs that are contraindicated in pregnancy on the basis of animal and human evidence and whose risk exceeds the benefits.

The specific mechanism of action is known or postulated for very few teratogens. Warfarin, an anticoagulant because it is a vitamin K antagonist, prevents the carboxylation of ?-carboxyglutamic acid, which is a component of osteocalcin and other vitamin K–dependent bone proteins. The teratogenic effect on developing cartilage, especially nasal cartilage, appears to be avoided if the pregnant woman's treatment between weeks 6 and 12 of gestation is switched from warfarin to heparin. Hypothyroidism in the fetus may be caused by the maternal ingestion of an excessive amount of iodides or propylthiouracil; each interferes with the conversion of inorganic to organic iodides. Phenytoin may be teratogenic because of the accumulation of a metabolite as a result of deficiency of epoxide hydrolase.

Recognition of teratogens offers the opportunity for prevention of related birth defects. For example, if a pregnant woman is informed of the potentially harmful effects of alcohol on her unborn infant, she may be motivated to control this problem during pregnancy. A woman with insulin-dependent diabetes mellitus may significantly decrease her risk for having a child with birth defects by achieving good control of her disease *before* conception.

85.6 Radiation (also see Chapter 700)

Accidental exposure of pregnant women to radiation is a common cause for anxiety in women, their families, and their physicians, usually about whether the fetus will have birth defects or genetic abnormalities. It is unlikely that exposure to diagnostic radiation will cause gene mutations; no increase in genetic abnormalities has been identified in the offspring exposed as unborn fetuses to the atomic bomb explosions in Japan in 1945.

A more realistic concern is whether the exposed human fetus will show birth defects or a higher incidence of malignancy. The recommended occupational limit of maternal exposure to radiation from all sources is 500 mrad for the entire 40 wk of a pregnancy. See Chapter 700 for a discussion of gonadal exposure in the mother and whole body exposure of the fetus. The limited data on human fetuses show that large doses of radiation (20,000–50,000 mrad) are harmful to the central nervous system, as evidenced by microcephaly, mental retardation, and IUGR.

Therapeutic abortion is often recommended when exposure exceeds 10,000 mrad. It is more likely that a human fetus will be exposed to 1,000–3,000 mrad, an amount not shown to cause malformations. Whether this level of fetal exposure is associated with an increased risk for childhood cancer or leukemia is controversial.

85.7 Intrauterine Diagnosis of Fetal Disease (see Table 85–1)

See section 85.2 for a discussion of fetal distress.

Diagnostic procedures are used to identify fetal diseases when abortion is being considered, when direct fetal treatment is possible, or when a decision is made to deliver a viable, but premature infant to avoid intrauterine fetal demise. Fetal assessment is also indicated in a broader context when the family, medical, or reproductive history of the mother suggests the presence of a high-risk pregnancy or a high-risk fetus (Chapters 84 and 85.3).

Various methods are used for identifying fetal disease (see Table 85–1). Fetal ultrasonographic imaging may detect fetal growth abnormalities (by biometric measurements of biparietal diameter, femoral length, or head or abdominal circumference) or fetal malformations (Fig. 85–5 (Figure Not Available)). Although 95% of fetuses whose biparietal diameter is 9.5?cm or more are at least 37 wk of gestation, the lungs of these fetuses may not be mature. Serial

Figure 85.7-5 (Figure Not Available) Assessment of fetal anatomy. *A*, Overall view of the uterus at 24 wk showing a longitudinal section of the fetus and an anterior placenta. *B*, Transverse section at the level of the lateral ventricle at 18 wk showing *(right)* prominent anterior horns of the lateral ventricles on either side of the midline echo of the falx. *C*, Cross section of the umbilical cord showing that the lumen of the umbilical vein is much wider than that of the two umbilical arteries. *D*, Fourchambered view of the heart at 18 wk with equal-sized ventricles shown above equal-sized atria. *E*, *(i)* Normal male genitals near term; *(ii)* hydrocele outlining a testicle within the scrotum projecting into a normal-sized pocket of amniotic fluid at 38 wk. Approximately 2% of male infants after birth have clinical evidence of a hydrocele that is often bilateral, not to be confused with subcutaneous edema occurring during vaginal breech birth. *F*, Section of a thigh near term showing thick subcutaneous tissue 4.6?mm between markers) above the femur of a fetus with macrosomia. *G*, Fetal face viewed from below showing (from right to left) the nose, alveolar margin, and chin at 20 wk. (From Special investigative procedures. In Beischer NA, Mackay EV, Colditz PB (editors): *Obstetrics and the Newborn*, 3rd ed. Philadelphia, WB Saunders, 1997.)

determination of growth velocity and the head-to-abdominal circumference ratio enhances the ability to detect IUGR. Real-time ultrasonography may identify placental abnormalities (abruptio placentae, placenta previa) and fetal anomalies such as hydrocephalus, neural tube defects, duodenal atresia, diaphragmatic hernia, renal agenesis, bladder outlet obstruction, congenital heart disease, limb abnormalities, sacrococcygeal teratoma, cystic hygroma, omphalocele, gastroschisis, and hydrops (Table 85–4).

Real-time ultrasonography also facilitates performance of *cordocentesis* and the BPP by imaging fetal breathing, body movements, tone, and amniotic fluid volume (see Table 85–2). *Doppler velocimetry* assesses fetal arterial blood flow (vascular resistance) (see Figs. 85–2 and 85–3). Roentgenographic examination of the fetus has been replaced by real-time ultrasonography, MRI, and fetoscopy.

Amniocentesis, the transabdominal withdrawal of amniotic fluid during pregnancy for diagnostic purposes (see Table 85–1), is frequently performed to determine the timing of the delivery of fetuses with erythroblastosis fetalis or the need for fetal transfusion. It is also done for genetic indications, usually between the 15th and 16th wk of gestation, with results available within 1–2 wk. The most common indication for genetic amniocentesis is advanced maternal age (the risk for chromosome abnormality at age 21 is 1:526 vs 1:8 at age 49). The amniotic fluid may be directly analyzed for amino acids, enzymes, hormones, and abnormal metabolic products, and amniotic fluid cells may be cultivated to permit detailed cytologic analysis for prenatal detection of chromosomal abnormalities and DNA-gene or enzymatic analysis for the detection of inborn metabolic errors. Analysis of amniotic fluid may also help in identifying neural tube defects (elevation of a-fetoprotein), adrenogenital syndrome (elevation of 17-ketosteroids and pregnanetriol), and thyroid dysfunction. Chorionic villus biopsy (transvaginal or transabdominal) performed in the 1st trimester also provides fetal cells but may pose a slightly increased risk for fetal loss or limb reduction defects. Fetal cells circulating in maternal blood and fetal DNA in maternal plasma are potential noninvasive sources of material for prenatal diagnosis. This new technology may eliminate the need for amniocentesis or chorionic villus sampling.

The best available chemical indices of fetal maturity are provided by determination of amniotic fluid creatinine and lecithin, which reflect the maturity of the fetal kidneys and lungs, respectively. Lecithin is produced in the lungs by type II alveolar cells and eventually reaches the amniotic fluid via the effluent from the trachea. Until the middle of the 3rd trimester, its concentration nearly equals that of sphingomyelin; thereafter, sphingomyelin remains constant in amniotic fluid while lecithin increases. By 35 wk, the lecithin:sphingomyelin (L:S) ratio averages about 2:1, indicative of lung maturity.

Earlier lung maturation may occur in the presence of severe premature separation of the placenta, premature rupture of the fetal membranes, narcotic addiction, or maternal hypertensive

TABLE 85.7-4 -- Significance of Fetal Ultrasonographic Anatomic Findings

Prenatal Observation	Definition	Differential Diagnosis	Significance	Postnatal Evaluation
Dilated cerebral ventricles	Ventriculomegaly =10?mm	Hydrocephalus Hydrancephalus Dandy-Walker cyst Agenesis of corpus callosum	Transient isolated ventriculomegaly common and benign. Persistent or progressive more worrisome. Identify associated cranial and extracranial anomalies	Serial head US or CT. Evaluate for extracranial anomalies
Choroid plexus cysts	1 – 3% incidence Size ~ 10?mm: unilateral or bilateral	Abnormal karyotype (trisomy 18, 21) Aneuploidy risk 1: 100 if isolated. ? Risk (1:3) with other anomalies. Risk ? if large, complex, or bilateral cysts or advanced maternal age	Often isolated, benign; resolves by 24–28 wk. Examine for other organ anomalies, then amniocentesis for karyotype	Head US or CT. Examine for extracranial anomalies; karyotype if indicated
Nuchal pad thickening	=6?mm at 15–20 wk; cystic hygroma	Trisomy 21, 18 Turner's syndrome (XO) Nonchromosomal syndromes Normal (~ 25%)	~ 50% have chromosome abnormalities Amniocentesis for karyotype	Evaluate for multiple organ malformations; karyotype if indicated

Dilated renal pelvis	Pyelectasis = 5 to 10?mm 0.6–1% incidence	UPJ obstruction Vesicoureteral reflux Posterior ureteral valves Etopic ureterocele Large-volume nonobstruction	Often “physiologic” and transient Reflux is common If > 10?mm or with caliectasis, consider pathologic cause. If large bladder, consider posterior urethral valves, megacystic syndrome	Repeat US; VCUG, prophylactic antibiotics
Echogenic bowel	0.6% incidence	CF, meconium peritonitis, trisomy 21 or 18, other chromosomal abnormalities CMV, toxoplasmosis, GI obstruction	Often normal (65%) 10% have CF 1.5% have aneuploidy	Sweat chloride and DNA testing Karyotype Surgery for obstruction TORCH evaluation
Stomach appearance	Small or absent or double bubble	Upper GI obstruction (esophageal atresia) Double bubble signifies duodenal atresia Abnormal karyotype Polyhydramnios Stomach in chest signifies diaphragmatic hernia	Must also consider neurologic disorders that reduce swallowing. Over 30% with double bubble have trisomy 21	Chromosomes, KUB if indicated, upper GI series, neurologic evaluation

US = ultrasonography; UPJ = ureteropelvic junction; VCUG = voiding cystourethrogram; CF = cystic fibrosis; CMV = cytomegalovirus; GI = gastrointestinal; TORCH = toxoplasmosis, other agents, rubella, CMV, herpes simplex; KUB = kidney, ureter, and bladder.

and renal vascular disease. A delay in pulmonary maturation may be associated with hydrops fetalis or maternal diabetes without vascular disease. The likelihood of hyaline membrane disease is greatly reduced with L:S ratios of 2:1 or more, although hypoxia, acidosis, and hypothermia may increase the risk despite this “mature” L:S ratio. Maternal and fetal blood have an L:S ratio of about 1:4; thus, contamination will not alter the significance of a ratio of 2:1 or more. Meconium contamination, storage, and centrifugation all may reduce the reliability of the L:S ratio.

Saturated phosphatidylcholine or phosphatidylglycerol concentrations in amniotic fluid may be more specific and sensitive predictors of pulmonary maturity, especially in high-risk pregnancies such as those occurring in women with diabetes (see Chapters 90 and 96.1).

Although amniocentesis can be carried out with little discomfort to the mother, even in experienced hands the procedure entails some small risk, such as direct damage to the fetus, placental puncture and bleeding with secondary damage to the fetus, stimulation of uterine contraction and premature labor, amnionitis, and maternal sensitization to fetal blood. The earlier in gestation that amniotic puncture is done, the greater the risk to the fetus. Using ultrasound for placental and fetal localization can reduce the risk. The procedure should be limited to cases in which the potential benefits of the findings will outweigh the risk.

Cordocentesis, or percutaneous umbilical blood sampling, is used to diagnose fetal hematologic abnormalities, genetic disorders, infections, and fetal acidosis (see Table 85–1). Under direct ultrasonographic visualization, a long needle is passed into the umbilical vein at its entrance to the placenta or fetal abdominal wall. Blood may be withdrawn to determine fetal hemoglobin, platelet concentration, lymphocyte DNA, the presence of infection, or Pa_{O_2} , pH, P_{CO_2} , and lactate levels. Transfusion or administration of drugs can be given through the umbilical vein (Table 85–5).

85.8 Treatment and Prevention of Fetal Disease

Management of fetal diseases continues to depend on coordinated advances in diagnostic accuracy and knowledge of the disease's

TABLE 85.8-5 -- **Fetal Therapy**

Disorder	Possible Treatment
Hematology	
Anemia with hydrops (erythroblastosis fetalis)	Umbilical vein packed red blood cell transfusion
Thalassemia	Fetal stem cell transplantation
Thrombocytopenia	
Isoimmune	Umbilical vein platelet transfusion, maternal intravenous immunoglobulin
Autoimmune (ITP)	Maternal steroids and intravenous immunoglobulin
Chronic granulomatous disease	Fetal stem cell transplantation
Metabolic-Endocrine	
Maternal phenylketonuria (PKU)	Phenylalanine restriction

Fetal galactosemia	Galactose-free diet[?]
Multiple carboxylase deficiency	Biotin if responsive
Methylmalonicacidemia	Vitamin B_{12} if responsive
21-Hydroxylase deficiency	Dexamethasone
Maternal diabetes mellitus	Tight insulin control during pregnancy, labor, and delivery
Fetal goiter	Maternal hyperthyroidism—maternal propylthiouracil
	Fetal hypothyroidism—intra-amniotic thyroxine
Bartter syndrome	Maternal indomethacin may prevent nephrocalcinosis and postnatal sodium losses
Fetal Distress	
Hypoxia	Maternal oxygen, position
Intrauterine growth restriction	Maternal oxygen, position, improve nutrition if deficient
Oligohydramnios, premature rupture of membranes with variable deceleration	Amnioinfusion (antepartum and intrapartum)
Polyhydramnios	Amnioreduction (serial), indomethacin (if due to ? urine output) if indicated
Supraventricular tachycardia	Maternal digoxin,[*] flecainide, procainamide, amiodarone, quinidine
Lupus anticoagulant	Maternal aspirin, prednisone
Meconium-stained fluid	Amnioinfusion
Congenital heart block	Dexamethasone, pacemaker (with hydrops)
Premature labor	Sympathomimetics, magnesium sulfate, antibiotics
Respiratory	
Pulmonary immaturity	Betamethasone
Bilateral chylothorax—pleural effusions	Thoracentesis, pleuroamniotic shunt
Congenital Abnormalities[†]	
Neural tube defects	Folate, vitamins (prevention); surgery[‡]
Diaphragmatic hernia	Surgery (correction or plug therapy) [?] [‡]
Obstructive uropathy (with oligohydramnios but without renal dysplasia)	>24 wk <32 wk, vesicoamniotic shunt plus amnioinfusion
Cystic adenomatoid malformation (with hydrops)	Pleuroamniotic shunt or resection[‡]
Fetal neck masses	Secure an airway[‡]
Infectious Disease	
Group B streptococcus	Ampicillin, penicillin (prevention)
Chorioamnionitis	Antibiotics
Toxoplasmosis	Spiramycin, pyrimethamine, sulfadiazine, and folic acid
Syphilis	Penicillin
Tuberculosis	Antituberculosis drugs
Lyme disease	Penicillin, ceftriaxone
Parvovirus	Intrauterine red blood cell transfusion for hydrops, severe anemia
Chlamydia trachomatis	Erythromycin
HIV-AIDS	Zidovudine (AZT) plus protease inhibitors
Cytomegalovirus	Ganciclovir by umbilical vein
Other	
Nonimmune hydrops (anemia)	Umbilical vein packed red blood cell transfusion
Narcotic abstinence (withdrawal)	Maternal low-dose methadone
Severe combined immunodeficiency disease	Fetal stem cell transplantation
Sacrococcygeal teratoma (with hydrops)	In utero resection or vessel obliteration
Twin-twin transfusion syndrome	Repeated amniocentesis, YAG laser photocoagulation of shared vessels
Twin reversed arterial perfusion syndrome (TRAP)	Digoxin, indomethacin, cord occlusion
Multifetal gestation	Selective reduction

? *Denotes possible but not proved efficacy.*
* *Drug of choice (may require percutaneous umbilical cord sampling and umbilical vein administration if hydrops is present). Most drug therapy is given to the mother, with subsequent placental passage to the fetus.*
† *Detailed fetal ultrasonography is needed to detect other anomalies; karyotype is also indicated.*
‡ *Ex utero intrapartum treatment permits surgery and other procedures.*

natural history; an understanding of fetal nutrition, pharmacology, immunology, and pathophysiology; the availability of antimicrobial and antiviral drugs; and therapeutic procedures. Progress in providing specific treatments for accurately diagnosed diseases has improved with the advent of real-time ultrasonography and

cordocentesis (see Tables 85–1 and 85–5).

The incidence of sensitization of Rh-negative women by Rh-positive fetuses has been reduced by prophylactic administration of Rh(D) immunoglobulin to mothers early in pregnancy and after each delivery or abortion, thus reducing the frequency of hemolytic disease in their subsequent offspring. Fetal erythroblastosis (Chapter 92) may be accurately diagnosed by amniotic fluid analysis and treated with intrauterine intraperitoneal or, more often, intraumbilical vein transfusions of packed Rh-negative blood cells to maintain the fetus until it is mature enough to have a reasonable chance of survival.

Fetal hypoxia or distress may now be diagnosed with moderate success. Treatment, however, remains limited to supplying the mother with high concentrations of oxygen, positioning the uterus to avoid vascular compression, and initiating operative delivery before severe fetal injury occurs.

Pharmacologic approaches to fetal immaturity (e.g., administration of steroids to the mother to accelerate fetal lung maturation and to decrease the incidence of respiratory distress syndrome [Chapter 90] in prematurely delivered infants) are successful. Inhibiting labor with ß-sympathomimetic tocolytic agents is unfortunately not successful in most patients with premature labor. Management of definitively diagnosed fetal genetic disease or congenital anomalies consists of parental counseling or abortion; rarely, high-dose vitamin therapy for a responsive inborn error of metabolism (e.g., biotin-dependent disorders) or fetal transfusion (with red blood cells or platelets) may be indicated. Fetal surgery (see Table 85–5) remains an experimental approach to therapy and is available only in a few highly specialized perinatal centers. The nature of the defect and its consequences, as well as ethical implications for the fetus and the parents, must be considered.

Chapter 86 - The High-Risk Infant

Barbara J. Stoll
Robert M. Kliegman

Infants at risk during the neonatal period should be identified as early as possible to decrease neonatal morbidity and mortality (see also Chapter 82). The term *high-risk infant* designates an infant who should be under close observation by experienced physicians and nurses. Infants in the high-risk category are listed in Box 86–1 . Approximately 9% of all births require special or neonatal intensive care. Usually needed for only a few days, such observation may last from a few hours to several months. Some institutions find it advantageous to provide a special or transitional care nursery for high-risk infants, often within the labor and delivery suite. This facility should be equipped and staffed similar to a neonatal intensive care area.

Examination of fresh *placenta, cord,* and *membranes* may alert the physician to newborn infants at high risk and may help confirm a diagnosis in a sick infant. Fetal blood loss may be indicated by placental pallor, **retroplacental hematoma,** and tears in the velamentous cords or chorionic blood vessels supplying the succenturiate lobes. **Placental edema** and subsequent immunoglobulin G deficiency in newborns may be associated with fetofetal transfusion syndrome, hydrops fetalis, congenital nephrosis, or hepatic disease. **Amnion nodosum** (granules on the amnion) and **oligohydramnios** are associated with pulmonary hypoplasia and renal agenesis, whereas small whitish **nodules** on the cord suggest a candidal infection. **Short cords** and non-coiled cords occur with chromosome abnormalities and omphalocele. True umbilical cord **knots** are seen in approximately 1% of births and are associated with a long cord, small fetal size, polyhydramnios, monoamniotic twinning, fetal demise, and low Apgar scores.

Chorioangiomas are associated with prematurity, abruptio, polyhydramnios, and intrauterine growth restriction (IUGR). **Meconium staining** suggests in utero stress and increases the risk for pneumonia, and opacity of the fetal placental surface suggests infection. **Single umbilical arteries** are associated with an increased incidence of congenital abnormalities.

Many infants who are born prematurely, are small for gestational age (SGA), have significant perinatal asphyxia, are breech, or are born with life-threatening congenital anomalies do not have previously identified risk factors. For any given duration of gestation, the lower the birthweight, the higher the neonatal mortality; for any given weight, the shorter the gestational duration, the higher the neonatal mortality (Fig. 86–1). The highest risk of neonatal mortality occurs in infants who weigh less than 1,000?g at birth and whose gestation was less than 30 wk. The lowest risk of neonatal mortality occurs in infants with a birthweight

Box 86-1. High-Risk Infants

DEMOGRAPHIC SOCIAL FACTORS

- Maternal age <16 or >40 yr
- Illicit drug, alcohol, cigarette use
- Poverty
- Unmarried
- Emotional or physical stress

PAST MEDICAL HISTORY

- Genetic disorders
- Diabetes mellitus
- Hypertension
- Asymptomatic bacteriuria
- Rheumatologic illness (SLE)
- Long-term medication (see Tables 85–3 and 85–4)

PREVIOUS PREGNANCY

- Intrauterine fetal demise
- Neonatal death
- Prematurity
- Intrauterine growth restriction
- Congenital malformation

- Prematurity
- Intrauterine growth restriction
- Congenital malformation
- Incompetent cervix
- Blood group sensitization, neonatal jaundice
- Neonatal thrombocytopenia
- Hydrops
- Inborn errors of metabolism

PRESENT PREGNANCY

- Vaginal bleeding (abruptio placentae, placenta previa)
- Sexually transmitted diseases (colonization: herpes simplex, group B streptococcus), chlamydia, syphilis, hepatitis B, HIV
- Multiple gestation
- Preeclampsia
- Premature rupture of membranes
- Short interpregnancy time
- Poly-oligohydramnios
- Acute medical or surgical illness
- Inadequate prenatal care
- Familial or acquired hypercoagulable states
- Treatment of infertility

LABOR AND DELIVERY

- Premature labor (<37 wk)
- Postdates (>42 wk)
- Fetal distress

- Premature labor (<37 wk)
- Postdates (>42 wk)
- Fetal distress

- Immature L:S ratio; absent phosphatidylglycerol
- Breech presentation
- Meconium-stained fluid
- Nuchal cord
- Cesarean section
- Forceps delivery
- Apgar score <4 at 1?min

NEONATE

- Birthweight <2,500 or >4,000?g
- Birth before 37 or after 42 wk of gestation
- SGA, LGA growth status
- Tachypnea, cyanosis
- Congenital malformation
- Pallor, plethora, petechiae

SLE = systemic lupus erythematosus; L:S = lecithin:sphingomyelin ratio; SGA = small for gestational age; LGA = large for gestational age.

Figure 86-1 Estimated mortality risk by birthweight and gestational age based on singleton infants in NICHD Neonatal Research Network Centers between January 1, 1995, and December 31, 1996. (From Lemons JA, Bauers CR, OH W, et al: Very low birthweight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996. *Pediatrics* 2001;107. (http://www.pediatrics.org.cgi/content/full/107/1/e1)

of 3,000–4,000?g and a gestational age of 38–42 wk. As birthweight increases from 500 to 3,000?g, a logarithmic decrease in neonatal mortality occurs; for every week

increase in gestational age from the 25th to the 37th wk, the neonatal mortality rate decreases by approximately half. Nevertheless, approximately 40% of all *perinatal deaths* occur after 37 wk of gestation in infants weighing 2,500?g or more; many of these deaths take place in the period immediately before birth and are more readily preventable than those of smaller and more immature infants. In addition, neonatal mortality rates rise sharply for infants weighing over 4,000?g at birth and for those whose gestational period is 42 wk or longer. Because neonatal mortality largely depends on birthweight and gestational age, Figure 86–1 can be used to help identify high-risk infants quickly. However, this analysis is based on total live births and therefore describes the mortality risk only *at birth.* Because most neonatal mortality occurs within the first hours and days after birth, the outlook improves dramatically with increasing postnatal survival. **REFERENCES**

86.1 Multiple Pregnancies

Incidence.

The reported incidence of spontaneous twinning is highest among blacks and East Indians, followed by northern European whites, and it is lowest in the Asian races. Specific rates include 1/56 in Belgium, 1/70 in American blacks; 1/86 in Italy; 1/88 in American whites; 1/130 in Greece; 1/150 in Japan; and 1/300 in China. Differences in the incidence of twins mainly involve fraternal (polyovular) dizygotic twins. Triplets are estimated to occur in 1 in 86^2 pregnancies and quadruplets in 1 in 86^3 pregnancies in the United States. The incidence of monozygotic twins is unaffected by racial or familial factors (3–5/1,000). The incidence of twins detected by ultrasonography at 12 wk of gestation (3–5%) is much higher than that occurring later in pregnancy; the vanishing twin syndrome results in a singleton fetus. Although the incidence of spontaneous multifetal gestation is stable, the overall incidence is increasing as a result of treatment of infertility with ovarian stimulants (clomiphene, gonadotropins) and in vitro fertilization. Twins represent about 2.5% of births but 20% of very low birthweight (VLBW) infants.

Etiology.

The occurrence of monovular twins appears to be independent of genetic influence. Polyovular pregnancies are more frequent beyond the 2nd pregnancy, in older women, and in families with a history of polyovular twins. They may result from simultaneous maturation of multiple ovarian follicles, but follicles containing two ova have been described as a genetic trait leading to twin pregnancies. Twin-prone women have higher levels of gonadotropin. Polyovular pregnancies occur in many women treated for infertility.

Conjoined twins (Siamese twins—incidence, 1/50,000) probably result from relatively late monovular separation, as does the presence of two separate embryos in one amniotic sac. The latter condition has a high fatality rate that is due to obstruction of the circulation secondary to intertwining of the umbilical cords. The

prognosis for conjoined twins depends on the possibility of surgical separation, which in turn depends on the degree that vital organs are shared. The site of connections varies: thoraco-omphalopagus (28% of conjoined twins), thoracopagus (18%), omphalopagus (10%), craniopagus (6%), and incomplete duplication (10%). Most conjoined twins are female.

Superfecundation, or fertilization of an ovum by an insemination that takes place after one ovum has already been fertilized, and *superfetation,* or fertilization and subsequent development of an ovum when a fetus is already present in the uterus, have been proposed as uncommon explanations for differences in size and appearance of certain twins at birth.

A *prenatal diagnosis of pregnancy with twins* is suggested by a uterine size that is greater than that expected for gestational age, auscultation of two fetal hearts, and elevated maternal serum a-fetoprotein or human chorionic gonadotropin levels, and it is confirmed by ultrasound. Ninety per cent of twins are detected before delivery.

Monozygotic vs Dizygotic Twins.

Identifying twins as monozygotic or dizygotic (monovular or polyovular) is important because studying monozygotic twins is useful in determining the relative influence of heredity and environment on human development and disease. Twins not of the same sex are dizygotic. In twins of the same sex, zygosity should be determined and recorded at birth through careful examination of the placenta or later through comparison of physical characteristics, detailed blood typing, DNA fingerprinting, or tissue (HLA) typing. Monozygotic twins may have physical and cognitive differences because their in utero environment may be different; differences may exist in the mitochondrial genome, in post-translational gene product modification, and in the expression of nuclear genes in response to environmental factors (nutrition).

EXAMINATION OF THE PLACENTA.

If the placentas are separate, they are always dichorionic (present in 75%), but the twins are not necessarily dizygotic because initiation of monovular twinning at the 1st cell division or during the morula stage may result in two amnions, two chorions, and even two placentas. One third of monozygotic twins are dichorionic and diamnionic.

An apparently single placenta may be present with either monovular or polyovular twins, yet inspection of a polyovular placenta usually reveals that each twin has a separate chorion that crosses the placenta between the attachments of the cords and two amnions. Separate or fused dichorionic placentas may be disproportionate in size. The fetus attached to the smaller placenta or the smaller portion of the placenta is usually smaller than its twin or is malformed. Monochorionic twins may be presumed to be monovular. They are usually diamnionic, and almost invariably, the placenta is a single mass.

Problems of twin gestation include polyhydramnios, hyperemesis gravidarum, preeclampsia, premature rupture of membranes, vasa previa, velamentous insertion of the umbilical cord, abnormal presentations (breech), and premature labor. When compared with the first-born twin, the second or B twin is at increased risk for respiratory distress syndrome and asphyxia. Twins are at risk for IUGR, twin-twin transfusion, and congenital anomalies, which occur predominantly in monozygotic twins. Anomalies are due to compression deformation of the uterus from crowding (hip dislocation), vascular communication with embolization (ileal atresia, porencephaly, cutis aplasia) or without embolization (acardiac twin), and unknown factors that cause twinning (conjoined twins, anencephaly, meningomyelocele).

Placental vascular anastomoses occur with high frequency only in monochorionic twins. In monochorionic placentas, the fetal vasculature is usually joined, sometimes in a very complex manner. The vascular anastomoses in monochorionic placentas may be artery to artery, vein to vein, or artery to vein. They are usually well enough balanced so that neither twin suffers. Artery-to-artery communications cross over placental veins, and when anastomoses are present, blood can readily be stroked from one fetal vascular bed to the other. Vein-to-vein communications are similarly recognized but are less common. A combination of artery-to-artery and vein-to-vein anastomoses is associated with the condition of lethal *acardiac fetus.* This rare lethal anomaly (1/35,000) is secondary to the TRAP sequence—twin reversed arterial perfusion. Nd:YAG laser ablation of the anastomosis or cord occlusion in utero can be used to treat heart failure in the surviving twin. In rare cases, one umbilical cord may arise from the other after leaving the placenta. In such cases, the twin attached to the secondary cord is usually malformed or dies in utero. Table 86–1 lists the more frequent changes associated with a large uncompensated arteriovenous shunt from the placenta of one twin to that of the other; twins of widely discrepant size are usually monochorionic.

In the **fetal transfusion syndrome,** an artery from one twin acutely or chronically delivers blood that is drained into the vein of the other. The latter becomes plethoric and large, and the former is anemic and small. Generally, with chronicity, a 5?g/dL hemoglobin and 20% body weight difference can be noted in this syndrome. Maternal hydramnios in a twin pregnancy suggests fetal transfusion syndrome.

Anticipating this possibility by preparing to transfuse the donor twin or bleed the recipient twin may be lifesaving. Death of the donor twin in utero may result in generalized fibrin thrombi in the smaller arterioles of the recipient twin, possibly as the result of transfusion of thromboplastin-rich blood from the macerating donor fetus. Disseminated intravascular coagulation may develop in the surviving twin. Treatment of this highly lethal problem includes maternal digoxin, aggressive amnioreduction for polyhydramnios, selective twin termination, or Nd:YAG laser or fetoscopic ablation of the anastomosis.

POSTNATAL IDENTIFICATION.

The following ***physical criteria*** can be used to determine whether twins are monovular: (1) both must be of the same sex; (2) their features, including ears and teeth, must be obviously alike (but they need not resemble each other more than the lateral halves of one individual); (3) their hair must be identical in color, texture, natural curl, and distribution; (4) their eyes must be of the same color and shade; (5) their skin must be of the same texture and color (nevi may be differently apportioned and distributed); (6) their hands and feet must be of the same conformation and of similar size; and (7) their anthropometric values must show close agreement.

Prognosis.

Most twins are born prematurely, and maternal complications of pregnancy are more common than with single pregnancies. Although monochorionic twins have a significant increase in perinatal mortality, there is no significant difference between the neonatal mortality rates of twin and single births in comparable weight groups. Because most twins are premature by weight, their overall mortality is higher than that of single

TABLE 86.1-1 -- **Characteristic Changes in Monochorionic Twins with Uncompensated Placental Arteriovenous Shunts**

Twin on	
Arterial Side—Donor	***Venous Side—Recipient***
Prematurity	Prematurity
Oligohydramnios	Polyhydramnios
Small premature	Hydrops
Malnourished	Large premature
Pale	Well nourished
Anemic	Plethoric
Hypovolemia	Polycythemic
Hypoglycemia	Hypervolemic
Microcardia	Cardiac hypertrophy

Glomeruli small or normal	Myocardial dysfunction
Arterioles thin walled	Tricuspid valve regurgitation
	Right ventricular outflow obstruction
	Glomeruli large
	Arterioles thick walled

births. The perinatal mortality of twins is about four times that of singletons. Monoamnionic twins have an increased likelihood of entangling their cords, which may lead to asphyxia. Theoretically, the 2nd twin is more subject to anoxia than the 1st because the placenta may separate after birth of the 1st twin and before birth of the 2nd. In addition, delivery of the 2nd twin may be difficult because it may be in an abnormal presentation (breech, entangled), uterine tone may be decreased, or the cervix may begin to close after the 1st twin's birth. A growth-retarded twin is at high risk for hypoglycemia. Any notable difference in the size of monovular twins at birth usually disappears by the time that the infants are 6 mo of age. The mortality for multiple gestations with four or more fetuses is excessively high for each fetus. Because of this poor prognosis, selective fetal reduction (with transabdominal intrathoracic injection of KCl) to two to three fetuses has been offered as a treatment option. Monozygotic twins have an increased risk of one twin dying in utero. The surviving twin has a greater risk for cerebral palsy and other neurodevelopmental sequelae.

Treatment.

Prenatal diagnosis enables the obstetrician and pediatrician to anticipate the birth of infants who are at high risk because of twinning. Close observation is indicated during labor and in the immediate neonatal period so that prompt treatment of asphyxia or fetal transfusion syndrome can be initiated. The decision to perform an immediate blood transfusion in a severely anemic “donor twin” or to perform a partial exchange transfusion of a “recipient twin” must be based on clinical judgment.

86.2 Prematurity and Intrauterine Growth Retardation

Definitions.

Liveborn[*] infants delivered before 37 wk from the 1st day of the last menstrual period are termed *premature* by the World Health Organization. Low birthweight (LBW; birthweight of 2500?g or less) is due to prematurity, poor intrauterine growth (IUGR, also referred to as *SGA),* or both. Prematurity and IUGR are associated with increased neonatal morbidity and mortality. Ideally, definitions of LBW for individual populations should be based on data that are as genetically and environmentally homogeneous as possible. Figure 86–1 presents variations in neonatal mortality based on birthweight, gestational age, and gender.

Incidence.

In 2000, 7.6% of liveborn neonates in the United States weighed less than 2,500?g; the rate for blacks was almost twice that for whites. Over the past 2 decades, the LBW rate has increased primarily because of an increased number of preterm births. Women whose 1st births are delivered before term are at increased risk for recurrent preterm delivery. Approximately 30% of LBW infants in the United States have IUGR and are born after 37 wk. At LBW rates greater than 10%, the contribution of IUGR increases and that of prematurity decreases. In developing countries, approximately 70% of LBW infants have IUGR. Infants with IUGR have greater morbidity and mortality than do appropriately grown, gestational age–matched infants (see Fig. 86–1).

Very Low Birthweight Infants.

VLBW infants weigh less than 1,500?g and are predominantly premature. In the United States in 2000, the VLBW rate was approximately 1.4%, 3.1% in blacks and 1.1% in whites. The VLBW rate is an accurate predictor of the infant mortality rate. VLBW infants account for over 50% of neonatal deaths and 50% of handicapped infants; their survival is directly related to birthweight, with approximately 20% of those between 500 and 600?g and over 90% of those between 1,250 and 1,500?g surviving. The VLBW rate has remained unchanged for black Americans but has increased in whites, perhaps because of a rise in multiple births in whites. Perinatal care has improved the rate of survival of LBW infants. When compared with term infants, VLBW neonates have a higher incidence of rehospitalization during the 1st yr of life for sequelae of prematurity, infections, neurologic complications, and psychosocial disorders (see later discussion in this section on prognosis).

Factors Related to Premature Birth and Low Birthweight.

It is difficult to completely separate factors associated with prematurity from those associated with IUGR (see also Chapters 83 and 84). A strong positive correlation exists between both preterm birth and IUGR and low socioeconomic status. Families of low socioeconomic status have higher rates of maternal undernutrition, anemia, and illness; inadequate prenatal care; drug misuse; obstetric complications; and maternal histories of reproductive inefficiency (abortions, stillbirths, premature or LBW infants). Other associated factors such as single-parent families, teenage pregnancies, short inter-pregnancy interval, and mothers who have borne more than four previous children are also encountered more frequently. Systematic differences in fetal growth have also been described in association with maternal size, birth order, sibling weight, social class, maternal smoking, and other factors. The degree to which the variance in birthweight among various populations is due to environmental (extrafetal) rather than genetic differences in growth potential is difficult to determine.

The etiology of preterm birth is multifactorial and involves a complex interaction between fetal, placental, uterine, and maternal factors (Box 86–2).

Premature birth of infants whose LBW is appropriate for their preterm gestational age is associated with medical conditions characterized by an inability of the uterus to retain the fetus, interference with the course of the pregnancy, premature rupture of the amniotic membranes or premature separation of the placenta, or an undetermined stimulus to effective uterine contractions before term.

Overt or asymptomatic bacterial infection (group B streptococci, *Listeria monocytogenes, Ureaplasma urealyticum, Mycoplasma*

* Live birth is defined by the World Health Assembly (1950) as “the complete expulsion or extraction from its mother of a product of conception which, after such separation, breathes or shows any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of the voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached.” This definition is approved by the American Public Health Association.

hominis, Chlamydia, Trichomonas vaginalis, Gardnerella vaginalis, Bacteroides spp.) of the amniotic fluid and membranes (chorioamnionitis) may initiate preterm labor. Bacterial products may stimulate the production of local inflammatory mediators (interleukin 6, prostaglandins), which may induce premature uterine contractions or a local inflammatory response with focal membrane rupture. Appropriate antibiotic therapy reduces the risk of fetal infection and may prolong gestation. The use of ß-sympathomimetic receptor agonists (ritodrine, terbutaline) has not prevented premature birth. Other agents (indomethacin) can lead to significant neonatal complications.

IUGR is associated with medical conditions that interfere with the circulation and efficiency of the placenta, with the development or growth of the fetus, or with the general health and nutrition of the mother (Box 86–3). Many factors are common to both prematurely born and LBW infants with IUGR. IUGR is associated with decreased insulin production or insulin (or insulin-like growth factor [IGF]) action at the receptor level. Infants with IGF-I receptor defects, pancreatic hypoplasia, or transient neonatal diabetes have IUGR. Genetic mutations affecting the glucose-sensing mechanisms of the pancreatic islet cells that result in decreased insulin release (loss of function of the glucose-sensing glucokinase gene) give rise to IUGR.

IUGR may be a normal fetal response to nutritional or oxygen deprivation. Therefore, the issue is not the IUGR but rather the ongoing risk of malnutrition or hypoxia. Similarly, some preterm births signify a need for early delivery from a potentially disadvantageous intrauterine environment. IUGR is often classified as reduced growth that is symmetric (head circumference, length, and weight equally affected) or asymmetric (with relative sparing of head growth) (see Fig. 85–1). Symmetric IUGR often has an earlier onset and is associated with diseases that seriously affect fetal cell number, such as conditions with chromosomal, genetic, malformation, teratogenic, infectious, or severe maternal hypertensive etiologies. Asymmetric IUGR is often of late onset, demonstrates preservation of Doppler waveform velocity to the carotid vessels, and is associated with poor maternal nutrition or with late onset or exacerbation of maternal vascular disease (preeclampsia, chronic hypertension). Problems of infants with IUGR are noted in Table 86–2 .

Assessment of Gestational Age at Birth.

When compared with a premature infant of appropriate weight, an infant with IUGR has a reduced birthweight and may appear to have a *disproportionately larger head relative to body size*; infants in both groups lack subcutaneous fat. Neurologic maturity (e.g., nerve conduction velocity), in the absence of asphyxia, correlates with gestational age despite reduced fetal weight. Physical signs may be useful in estimating gestational age at birth. Commonly used, the Ballard scoring system is accurate to ±2 wk (Figs. 86–2 to 86–4). An infant should be presumed to be at high risk for mortality or morbidity if a discrepancy exists between the estimation of gestational age by physical examination, the mother's estimated date of her last menstrual period, and fetal ultrasonic evaluation.

Spectrum of Disease in Low-Birthweight Infants.

Immaturity tends to increase the severity but reduce the distinctiveness of the clinical manifestations of most neonatal diseases. Immature

TABLE 86.2-2 -- Problems of IUGR (SGA) Infants

Problem	Pathogenesis
Intrauterine fetal demise	Hypoxia, acidosis, infection, lethal anomaly
Perinatal asphyxia	? Uteroplacental perfusion during labor ± chronic fetal hypoxia-acidosis; meconium aspiration syndrome
Hypoglycemia	? Tissue glycogen stores, ? gluconeogenesis, hyperinsulinism, ? glucose needs of hypoxia, hypothermia, large brain
Polycythemia-hyperviscosity	Fetal hypoxia with ? erythropoietin production
Reduced oxygen consumption/hypothermia	Hypoxia, hypoglycemia, starvation effect, poor subcutaneous fat stores
Dysmorphology	Syndrome anomalads, chromosomal-genetic disorders, oligohydramnios-induced deformations, TORCH infection
Other problems include pulmonary hemorrhage and those common to the gestational age–related risks of prematurity if born at less than 37 wk (see Box 86–4).	
IUGR = intrauterine growth restriction; SGA = small for gestational age;	
TORCH = toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.	

Figure 86.2-2 Physical criteria for maturity. The expanded New Ballard Score includes extremely premature infants and has been refined to improve accuracy in more mature infants. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard Score, expanded to include extremely premature infants. *J Pediatr* 1991;119:417.)

organ function, complications of therapy, and the specific disorders that caused the premature onset of labor contribute to neonatal morbidity and mortality associated with premature, LBW infants (Box 86–4). Among VLBW infants, morbidity is inversely related to birthweight. Respiratory distress syndrome is noted in approximately 80% of infants 501–750?g, in 65% of those 751–1,000?g, in 45% between 1,001 and 1,250?g, and in 25% between 1,251 and 1,500?g; severe intraventricular hemorrhage (IVH) is noted in approximately 25% of infants

501–750?g, in 12% between 751 and 1,000?g, in 8% between 1,001 and 1,250?g, and in 3% between 1,251 and 1,500?g. Overall, the risk of late sepsis (24%), bronchopulmonary dysplasia (23%), severe IVH (11%), necrotizing enterocolitis (7%),

and prolonged hospitalization (45–125 days) is high in VLBW infants. Problems associated with IUGR LBW infants are noted in Table 86–2 ; these added problems are often superimposed on those noted in Box 86–4 if an infant with IUGR is also premature. Poor postnatal growth is an important problem for both preterm and IUGR infants.

Nursery Care.

At birth, the measures needed for clearing the airway, initiating breathing, caring for the cord and eyes, and administering vitamin K are the same in immature infants as in those of normal weight and maturity (Chapter 83). Special care is required to maintain a patent airway and avoid potential aspiration of gastric contents. Additional considerations are the need for (1) thermal control and monitoring of the heart rate and respiration, (2) oxygen therapy, and (3) special attention to the details of feeding. Safeguards against infection can never be relaxed. Everyone involved must be aware that routine procedures that disturb these infants may result in hypoxia. The need for regular and active participation by the parents in the infant's care in the nursery, the need to instruct the mother in at-home care of her infant, and the

question of prognosis for later growth and development require special consideration.

THERMAL CONTROL.

The survival rate of LBW and sick infants is higher when they are cared for at or near their *neutral thermal environment.* This environment is a set of thermal conditions, including air and radiating surface temperatures, relative humidity, and airflow, at which heat production (measured as oxygen consumption) is minimal and the infant's core temperature is within the normal range. It is a function of the size and postnatal age of an infant; larger, older infants require lower environmental temperatures than smaller, younger infants do. Isolettes (incubators) or radiant warmers can be used to maintain body temperature. Body heat is conserved through provision of a warm environment and standard conditions of humidity. The optimal environmental temperature for minimal heat loss and oxygen consumption for an unclothed infant is one that maintains the infant's core temperature at 36.5–37.0°C. It depends on an infant's size and maturity; the smaller and more immature the infant, the higher the environmental temperature required. An additional Plexiglas heat shield or head cap and body clothing may be required to keep an extremely LBW (ELBW) preterm infant warm. Infant warmth can be maintained by heating the air to a desired temperature or by servo-controlling the infant's body temperature at a desired set point. Continuous monitoring of the infant's temperature is required so that the environmental temperature can be adjusted to maintain optimal body temperature.

Maintaining a relative *humidity* of 40–60% aids in stabilizing body temperature by reducing heat loss at lower environmental temperatures; by preventing drying and irritation of the lining of respiratory passages, especially during the administration of oxygen and after or during endotracheal intubation (usually 100% humidity); and by thinning viscid secretions and reducing insensible water loss from the lungs. An infant should be weaned and then removed from the isolette or radiant warmer only when the gradual change to the atmosphere of the nursery does not result in a significant change in the infant's temperature, color, activity, or vital signs.

Administering *oxygen* to reduce the risk of injury from hypoxia and circulatory insufficiency must be balanced against the risk of hyperoxia to the eyes (retinopathy of prematurity) and oxygen injury to the lungs. Oxygen should be administered via a head hood, nasal cannula, continuous positive airway pressure apparatus, or endotracheal tube to maintain stable and safe inspired oxygen concentrations. Although cyanosis must be treated immediately, oxygen is a drug and its use must be carefully regulated to maximize benefit and minimize potential harm. The concentration of inspired oxygen must be adjusted in accordance with the oxygen tension of arterial blood (Pa_{O_2}) or noninvasive methods such as continuous pulse oximetry or transcutaneous oxygen measurements. Capillary blood gases are inadequate for estimating arterial oxygen levels.

FLUID REQUIREMENTS.

Fluid needs vary according to gestational age, environmental conditions, and disease states. Assuming minimal water loss in the stool of infants not receiving oral fluids, their water needs are equal to their insensible water loss, excretion of renal solutes, growth, and any unusual ongoing losses. Insensible water loss is indirectly related to gestational age; very immature preterm infants (<1,000?g) may lose as much as 2–3?mL/kg/hr, partly because of immature skin, lack of subcutaneous tissue, and a large exposed surface area. Insensible water loss is increased under radiant warmers, during phototherapy, and in febrile infants. It is diminished when infants are clothed, are covered by a Plexiglas inner heat shield, breathe humidified air, or are of advanced postnatal age. Larger premature infants (2,000–2,500?g) nursed in an incubator may have an insensible water loss of approximately 0.6–0.7?mL/kg/hr.

Adequate fluid intake is essential for excretion of the urinary solute load (e.g., urea, electrolytes, phosphate). The amount varies with dietary intake and the anabolic or catabolic state of nutrition. Formulas with a high solute load, high protein intake, and catabolism increase the end products that require urinary excretion and thus increase the requirement for water. Renal solute loads may vary between 7.5 and 30?mOsm/kg. Newborn infants, especially those with VLBW, are also less able to concentrate urine; thus, their fluid intake required to excrete solutes increases.

Water intake in term infants is usually begun at 60–70?mL/kg on day 1 and increased to 100–120?mL/kg by days 2–3. Smaller, more premature infants may need to start with 70–80?mL/kg on day 1 and advance gradually to 150?mL/kg/day. Fluid volumes should be titrated individually, although it is unusual to exceed 150?mL/kg/24?hr. Infants weighing less than 750?g in the 1st wk of life have immature skin and a large surface area, characteristics that lead to a high rate of transepidermal fluid loss, at times requiring higher rates of intravenous fluids. Daily weights, urine, and serum urea nitrogen with electrolytes should be monitored carefully to determine water balance and fluid needs. Clinical observation and physical examination are poor indicators of the state of hydration of premature infants. Conditions that increase fluid loss, such as glycosuria, the polyuric phase of acute tubular necrosis, and diarrhea, may place additional strain on kidneys that have not yet acquired their maximal capacity to conserve water and electrolytes, the results of which may be severe dehydration. Alternatively, fluid overload may lead to edema, heart failure, patent ductus arteriosus, and bronchopulmonary dysplasia.

TOTAL PARENTERAL NUTRITION.

Before enteral feeding has been established or when enteral feeding is impossible for prolonged periods, total intravenous alimentation may provide sufficient fluid, calories, amino acids, electrolytes, and vitamins to sustain the growth of LBW infants. This technique has been lifesaving for ELBW infants and those who have had intractable diarrheal syndromes or extensive bowel resection. Infusions may be administered through a percutaneously or surgically placed indwelling central venous catheter or through a peripheral vein. The umbilical vein may also be used for a short time.

The goal of parenteral alimentation is to deliver sufficient calories from glucose, protein, and lipids to promote optimal growth. The infusate should contain 2.5–3?g/dL of synthetic amino acids and glucose usually in the range of 10–15?g/dL,

in addition to appropriate quantities of electrolytes, trace minerals, and vitamins. If a peripheral vein is used, it is advisable to keep the glucose concentration below 12.5?g/dL. If a central vein is used, glucose concentrations as high as 25?g/dL may be used (rarely). Intravenous fat emulsions such as 20% Intralipid (2.2?kcal/mL) may be administered to provide calories without an appreciable osmotic load, thereby decreasing the need for infusion of the higher concentrations of glucose by central or peripheral vein and usually preventing the development of essential fatty acid deficiency. Intralipid may be initiated at 0.5?g/kg/24?hr and advanced to 3?g/kg/24?hr, if triglyceride levels remain normal; 0.5?g/kg/24?hr is sufficient to prevent essential fatty acid deficiency. Electrolytes, trace minerals, and vitamin additives are included in amounts approximating established intravenous maintenance requirements. The content of each day's infusate should be determined after carefully assessing the infant's clinical and biochemical status. Slow and continuous infusion is advisable. A well-trained pharmacist should mix all solutions under a laminar flow hood.

After a caloric intake of greater than 100?kcal/kg/24?hr is established by total parenteral intravenous nutrition, LBW infants can be expected to gain about 15?g/kg/24?hr, with a positive nitrogen balance of 150–200?mg/kg/24?hr, in the absence of episodes of sepsis, surgical procedures, or other severe stress. This goal can usually be achieved (and the catabolic tendency during the 1st wk of life reversed with subsequent weight gain) by peripheral vein infusion of 2.5–3.5?g/kg/24?hr of an amino acid mixture, 10?g/dL of glucose, and 2–3?g/kg/24?hr of Intralipid.

Complications of intravenous alimentation are related to both the catheter and metabolism of the infusate. Sepsis is the most important problem of central vein infusions and can be minimized only by meticulous catheter care and aseptic preparation of the infusate. Coagulase-negative staphylococcus is the most common infecting organism. Treatment includes appropriate antibiotics. If an infection persists (repeatedly positive blood cultures while receiving appropriate antibiotics), the line must be removed. Thrombosis, extravasation of fluid, and accidental dislodgement of catheters have also occurred. Although sepsis is less often attributable to peripheral vein infusion, phlebitis, cutaneous sloughing, and superficial infection may occur. **Metabolic complications** of parenteral nutrition include hyperglycemia from the high glucose concentration of the infusate, which may lead to osmotic diuresis and dehydration; azotemia; a possible increased risk of nephrocalcinosis; hypoglycemia from sudden accidental cessation of the infusate; hyperlipidemia and possibly hypoxemia from intravenous lipid infusions; and hyperammonemia, which may be due to high levels of certain amino acids. Metabolic bone disease and/or cholestatic jaundice and liver disease may develop in infants who require long-term parenteral nutrition. Biochemical and physiologic monitoring of infants receiving intravenous alimentation is indicated because of the frequency and seriousness of complications.

FEEDING.

The method of feeding each LBW infant should be individualized. It is important to avoid fatigue and aspiration of food by regurgitation or by the feeding process. No feeding method averts these problems unless the person feeding the infant has been well trained in the method. Oral feeding (nipple) should not be initiated or should be discontinued in infants with respiratory distress, hypoxia, circulatory insufficiency, excessive secretions, gagging, sepsis, central nervous system depression, immaturity, or signs of serious illness. These high-risk infants require parenteral nutrition or gavage feeding to supply calories, fluid, and electrolytes. The process of oral alimentation requires, in addition to a strong sucking effort, coordination of swallowing, epiglottal and uvular closure of the larynx and nasal passages, and normal esophageal motility, a synchronized process that is usually absent before 34 wk gestation.

Preterm infants at 34 wk gestation or more can often be fed by bottle or at the breast. Because the effort of sucking is usually the limiting factor, breast-feeding is less likely to succeed until the infant matures. Bottle-feeding of expressed breast milk may be a temporary alternative. In *bottle-feeding,* effort may be reduced by use of special small, soft nipples with large holes. Smaller or less vigorous infants should be fed by *gavage*: a soft plastic tube with No. 5 French external and approximately 0.05?cm internal diameters and with a rounded atraumatic tip and two holes on alternate sides is preferable. The tube is passed through the nose until approximately 2.5?cm (1?inch) of the lower end is in the stomach. The free end of the tube has an adapter into which the tip of a syringe is fitted, and a measured amount of fluid is given by pump or by gravity. Such tubes may be left in place for 3–7 days before being replaced by a similar tube through the alternate nostril. Infants occasionally have enough local irritation from an indwelling tube that they may gag or troublesome secretions may gather around it in the nasopharynx. In such cases, a catheter may be passed through the mouth by a skilled person and removed at the end of each feeding.

An LBW infant may be fed with intermittent bolus feedings or continuous feeding. In the occasional infant with feeding intolerance, nasojejunal feeding may be successful. However, intestinal perforation is a risk with nasojejunal feeding. A change to

breast- or bottle-feeding may be instituted gradually as soon as an infant displays general vigor adequate for oral feeding without fatigue.

Gastrostomy feeding is not usually indicated in premature infants because of an associated increase in mortality, except as an adjunct to surgical management of specific gastrointestinal conditions or in permanently neurologically injured patients unable to suck and swallow normally.

Initiation of Feeding. The optimal time to introduce enteral feeding to a sick LBW infant is controversial. Trophic feeding is the practice of feeding very small amounts of enteral nourishment to VLBW preterm infants to stimulate development of the immature gastrointestinal tract. Many studies have demonstrated benefits of trophic feeding, including enhanced gut motility, improved growth, decreased need for parenteral nutrition, fewer episodes of sepsis, and shortened hospital stay. Once the infant is stable, small-volume feedings are given in addition to intravenous fluids/nutrition. Feeding is gradually advanced and parenteral nutrition decreased. This approach may reduce the incidence of necrotizing enterocolitis. The main principle in feeding premature infants is to proceed cautiously and gradually. Careful early feeding of breast milk or formula tends to reduce the risk of hypoglycemia,

dehydration, and hyperbilirubinemia without the additional risk of aspiration, provided that the presence of respiratory distress or other disorders does not present an indication for withholding oral feedings and administering electrolytes, fluids, and calories intravenously.

If an infant is well, is making sucking movements, and is in no distress, oral feeding may be attempted, although most infants weighing less than 1,500?g require tube feeding because they are unable to coordinate breathing, sucking, and swallowing. Intestinal tract readiness for feeding may be determined by active bowel sounds, passage of meconium, and the absence of abdominal distention, bilious gastric aspirates, or emesis. For infants under 1,000?g, the initial feedings are either half- or full-strength breast milk or preterm formula at 10?mL/kg/24?hr as a continuous nasogastric tube drip (or given by intermittent gavage every 2–3?hr). If the initial feeding is tolerated, the volume is increased by 10–15?mL/kg/24?hr. The daily milk volume increment should not exceed 20?mL/kg/24?hr. Once a volume of 150?mL/kg/24?hr has been achieved, the caloric content may be increased to 24 or 27?kcal/oz. With high caloric density, infants are at risk for dehydration, edema, lactose intolerance, diarrhea, flatus, and delayed gastric emptying with emesis. Intravenous fluids are needed until feedings provide approximately 120?mL/kg/24?hr. The feeding protocol for premature infants weighing over 1,500?g is initiated at a volume of 20–25?mL/kg/24?hr of full-strength breast milk or preterm formula given as a bolus every 3?hr. Thereafter, increments in total daily formula volume should not exceed 20?mL/kg/24?hr. The expected weight increments for premature infants of various birthweights are projected from Figure 86–5 . Infants with IUGR may not demonstrate the initial weight loss noted in premature infants.

Regurgitation, vomiting, abdominal distention, or gastric residuals from previous feedings should arouse suspicion of sepsis, necrotizing enterocolitis, or intestinal obstruction; these conditions are indications to drop back in the schedule and increase subsequent feedings slowly or to change to intravenous alimentation and evaluate for more serious problems (Chapter 91.2). Weight gain may not be achieved for 10–12 days, and a daily intake of 130–150?mL/kg or more may be necessary for some infants. Alternatively, in vigorous infants whose feeding schedule is advanced successfully in calories or volume, weight gain may appear within a few days.

When tube feeding is used, the contents of the stomach should be aspirated before each feeding. If only air or small amounts of mucus are obtained, the feeding is given as planned. If all or a substantial part of the previous feeding is aspirated, it is advisable to reduce the amount of the feeding and proceed more gradually with subsequent increases.

The digestive enzyme systems of infants older than 28 wk gestation are mature enough to permit adequate digestion and absorption of protein and carbohydrate. Fat is less well absorbed, primarily because of inadequate amounts of bile salt; unsaturated fats and the fat of human milk are absorbed better than those of cow's milk. The weight gain of infants weighing under 2,000?g at birth should be adequate when human milk or “humanized” milk premature formula (40% casein and 60% whey) with a protein intake of 2.25–2.75?g/kg/24?hr is fed. These two alternatives should provide all amino acids essential

Figure 86.2-5 Average daily weight (grams) vs postnatal age (days) for infants with birthweight ranges of 501–750?g, 751–1,000?g, 1,001–1,250?g, and 1,251–1,500?g (*dotted lines*), plotted with the curves of Dancis and colleagues for infants with birthweights of 750?g, 1,000?g, 1,250?g, and 1,500?g (*solid lines*). (From Wright K, Dawson JP, Fallis D, et al: New postnatal growth grids for very low birth weight infants. *Pediatrics* 1993; 91:922.)

for premature infants, including tyrosine, cystine, and histidine. Higher protein intake may be well tolerated and is generally safe, especially in older, rapidly growing infants. However, protein intake as high as 4–5?g/kg/24?hr may be hazardous: although linear growth may be promoted, high-protein formulas may cause abnormal plasma aminograms; elevations in blood urea nitrogen, ammonia, and sodium concentrations; metabolic acidosis (cow's milk formulas); and untoward effects on neurologic development. Furthermore, the high protein and mineral contents of balanced cow's milk formulas with a high caloric content constitute a large solute load for the kidneys, a fact important in maintaining water balance, especially in infants with diarrhea or fever.

Breast milk from the infant's mother is the preferred milk for all infants, including VLBW infants. In addition to nutritional advantages, the benefits of breast milk include protection against a wide range of infections (through both specific and nonspecific anti-infective factors in breast milk and beneficial effects on intestinal flora), a decreased risk of necrotizing enterocolitis in preterm infants, a lower risk of sudden infant death syndrome, and possible long-term effects, including a lower risk of childhood/adolescent obesity and improved neurodevelopmental outcome. Once a premature infant takes 120?mL/kg/ 24?hr, breast milk fortifiers are added to supplement breast milk with protein, calcium, and phosphorus. If breast milk is unavailable, special preterm formulas should be used. At approximately 34–36 wk gestation, infants who are not receiving breast milk should be switched to a term formula (unless metabolic bone disease is present—see Chapter 95) because hypercalcemia may develop as a result of the preterm formula's higher calcium and vitamin D levels.

Although formula in amounts necessary for adequate growth probably contains adequate quantities of all vitamins, the volume of milk sufficient to satisfy these requirements may not be ingested for several weeks. Therefore, LBW infants should be given supplemental vitamins. Because requirements for these infants have not been precisely established, the recommended daily allowances for term infants should be given (see Chapter 40.7). Furthermore, these infants may have a special need for certain vitamins. Intermediary metabolism of phenylalanine and tyrosine depends, in part, on vitamin C. Decreased fat absorption with increased fecal fat loss may be associated with decreased absorption of *vitamin D,* other fat-soluble vitamins, and calcium in premature infants. VLBW infants are particularly prone to the development of rickets, but their total intake of vitamin D should not exceed 1,500?IU/24?hr. *Folic acid* is essential for the formation of DNA and production of new cells; serum and erythrocyte levels decrease in preterm infants during the first few weeks of life and remain low for 2–3 mo. Therefore, supplementation is recommended, although it does not result in improved growth or an increased hemoglobin concentration. Deficiency of vitamin E is uncommon but is associated with increased hemolysis and, if severe, with anemia in premature infants. Vitamin E

functions as an antioxidant to prevent the peroxidation of excessive polyunsaturated fatty acids in red blood cell membranes; its need may increase because of the increased membrane content of these fatty acids from older formulas with high polyunsaturated fatty acids. Vitamin A supplementation has been shown to reduce bronchopulmonary dysplasia in VLBW infants. Vitamin K deficiency is discussed in Chapter 92.4.

In LBW infants, physiologic anemia as a result of postnatal suppression of erythropoiesis is exacerbated by smaller fetal iron stores and greater expansion of blood volume from the more rapid growth than that of term infants; therefore, the anemia develops earlier and reaches a lower ultimate level. Fetal or neonatal blood loss accentuates this problem. Iron stores, even in VLBW neonates, are usually adequate until an infant's birthweight has doubled or after an infant has been treated with erythropoietin (Chapter 92); iron supplementation (2?mg/kg/ 24?hr) should then be started.

Properly fed premature infants may have from one to six daily stools of semisolid consistency; a sudden increase in their number, the appearance of occult or gross blood, or change to a watery consistency is more reason for concern than any arbitrarily stated frequency. Premature infants should not vomit or regurgitate. They should be satisfied and relaxed after a feeding but may normally show the activity of hunger shortly before the next feeding.

Prevention of Infection.

Premature infants have an increased susceptibility to infection, and thus meticulous attention to infection control is required. Prevention strategies include strict compliance with handwashing and universal precautions, limiting nurse-to-patient ratios and avoiding crowding, minimizing the risk of catheter contamination, meticulous skin care, encouraging early appropriate advancement of enteral feeding, education and feedback to staff, and surveillance of nosocomial infection rates in the nursery. Although no one with an infection should be permitted in the nursery, the risks of infection must be balanced against the disadvantages of limiting the infant's contact with the family. Early and frequent participation by parents in the nursery care of their infant does not significantly increase the risk of infection when preventive precautions are maintained. Routine immunizations should be given on the regular schedule at standard doses (Chapter 282).

Preventing transmission of infection from infant to infant is difficult because often neither term nor premature newborn infants have clear clinical evidence of an infection early in its course. Universal precautions require gloves to be worn with all patient contact. When epidemics occur within a nursery, cohort nursing and isolation rooms should be used.

Immaturity of Drug Metabolism.

Renal clearance of almost all substances excreted in the urine is diminished in newborn infants, but more so in premature ones. Intervals between doses may therefore need to be extended when administering drugs excreted chiefly by the kidneys. For instance, highly satisfactory levels of penicillin, gentamicin, and kanamycin are maintained by giving doses at 12?hr intervals. Longer intervals are required for many drugs administered to preterm infants. Drugs detoxified in the liver or requiring chemical conjugation before renal excretion should also be given with caution and in doses smaller than usual.

When possible, blood levels should be determined for potentially toxic drugs, especially if renal or hepatic dysfunction is present. Decisions about the choice and dose of antibacterial agents and the route of administration should be made on an individual basis rather than routinely because of the dangers of (1) development of infections with organisms resistant to antibacterial agents, (2) destruction or inhibition of intestinal bacteria that manufacture significant amounts of essential vitamins (e.g., vitamin K and thiamine), and (3) harmful interference in important metabolic processes.

Many drugs apparently safe for adults on the basis of toxicity studies may be harmful to newborn infants, especially premature ones. Oxygen and a number of drugs have proved toxic to premature infants in amounts not harmful to term infants (Table 86–3). Thus, administering any drug, particularly in large doses, without pharmacologic testing in premature infants should be undertaken carefully after weighing risks against benefits.

Prognosis.

Infants born weighing 1,501–2,500?g now have a 95% or greater chance of survival, but those weighing less still have significantly higher mortality (see Fig. 86–1). Intensive care has extended the period during which a VLBW infant is at increased risk of dying of complications of prematurity, such as bronchopulmonary dysplasia, necrotizing enterocolitis, or nosocomial

TABLE 86.2-3 -- Potential Adverse Reactions to Drugs Administered to Premature Infants

Drug	Reaction
Oxygen	Retinopathy of prematurity, bronchopulmonary dysplasia
Sulfisoxazole	Kernicterus
Chloramphenicol	Gray baby—shock, bone marrow suppression
Vitamin K analogs	Jaundice
Novobiocin	Jaundice

Hexachlorophene	Encephalopathy
Benzyl alcohol	Acidosis, collapse, intraventricular bleeding
Intravenous vitamin E	Ascites, shock
Phenolic detergents	Jaundice
$NaHCO_3$	Intraventricular hemorrhage
Amphotericin	Anuric renal failure, hypokalemia, hypomagnesemia
Reserpine	Nasal stuffiness
Indomethacin	Oliguria, hyponatremia, intestinal perforation
Cisapride	Prolonged Q-Tc interval
Tetracycline	Enamel hypoplasia
Tolazoline	Hypotension, gastrointestinal bleeding
Calcium salts	Subcutaneous necrosis
Aminoglycosides	Deafness, renal toxicity
Enteric gentamicin	Resistant bacteria
Prostaglandins	Seizures, diarrhea, apnea, hyperostosis, pyloric stenosis
Phenobarbital	Altered state, drowsiness
Morphine	Hypotension, urine retention, withdrawal
Pancuronium/vecuronium	Edema, hypovolemia, hypotension, tachycardia, contractions, prolonged hypotonia
Iodine antiseptics	Hypothyroidism, goiter
Fentanyl	Seizures, chest wall rigidity, withdrawal
Dexamethasone	Gastrointestinal bleeding, hypertension, infection, hyperglycemia, cardiomyopathy, reduced growth
Furosemide	Deafness, hyponatremia, hypokalemia, hypochloremia, nephrocalcinosis, biliary stones
Heparin (not low-dose prophylactic use)	Bleeding, intraventricular hemorrhage, thrombocytopenia
Erythromycin	Pyloric stenosis

infection (Box 86–5). The post-discharge mortality rate of LBW infants is higher than that of term infants during the 1st 2 yr of life. Because many of these deaths are attributable to infection (e.g., respiratory syncytial virus [RSV]), they are at least theoretically preventable. In addition, premature infants have an increased incidence of failure to thrive, sudden infant death syndrome, child abuse, and inadequate maternal-infant bonding. The biologic risk associated with poor cardiorespiratory regulation because of immaturity or complications of underlying perinatal disease and the social risk associated with poverty also contribute to the high mortality and morbidity of these infants. Congenital anomalies are present in approximately 3–7% of LBW infants.

In the absence of congenital abnormalities, central nervous system injury, VLBW or marked IUGR, the physical growth of LBW infants tends to approximate that of term infants by the 2nd yr; it occurs earlier in premature infants with larger birth size. VLBW infants may not catch up, especially if they have severe chronic sequelae, insufficient nutritional intake, or an inadequate caretaking environment (see Box 86–5). Premature birth in itself may prejudice later development. In general, the greater the immaturity and the lower the birthweight, the greater the likelihood of

intellectual and neurologic deficit; as many as 50% of 500–750?g infants have a significant neurodevelopmental handicap (blindness, deafness, mental retardation, cerebral palsy). Small head circumference at birth may be similarly related to a poor neurobehavioral prognosis. Children born after in vitro fertilization have an increased risk of neurologic impairment, especially cerebral palsy. This finding is probably explained by the increased risk associated with prematurity and multiple births, but the long-term safety of the procedure needs to be monitored. Many surviving LBW infants have hypotonia before 8 mo corrected age, which improves by the time that they are 8 mo–1 yr old. This transient hypotonia is not a poor prognostic sign. Thirty to 50% of VLBW children have poor school performance at 7 yr of age (repeat grades, special classes, learning

Box 86.2-5. Sequelae of Low Birthweight

IMMEDIATE	LATE
Hypoxia, ischemia	Mental retardation, spastic diplegia, microcephaly, seizures, poor school performance
Intraventricular hemorrhage	Mental retardation, spasticity, seizures, hydrocephalus
Sensorineural injury	Hearing, visual impairment, retinopathy of prematurity, strabismus, myopia
Respiratory failure	Bronchopulmonary dysplasia, cor pulmonale, bronchospasm, malnutrition, subglottic stenosis, iatrogenic cleft palate, recurrent pneumonia
Necrotizing enterocolitis	Short-bowel syndrome, malabsorption, malnutrition, infectious diarrhea
Cholestatic liver disease	Cirrhosis, hepatic failure, carcinoma, malnutrition
Nutrient deficiency	Osteopenia, fractures, anemia, vitamin E, growth failure
Social stress	Child abuse or neglect, failure to thrive, divorce
Other	Sudden infant death syndrome, infections, inguinal hernia, cutaneous scars (chest tube, patent ductus arteriosus ligation, intravenous infiltration), gastroesophageal reflux, hypertension, craniosynostosis, cholelithiasis, nephrocalcinosis, cutaneous hemangiomas

disorders, poor speech and language), despite a normal IQ. Factors posing a risk for poor academic performance include birthweight below 750?g, severe IVH, periventricular leukomalacia, bronchopulmonary dysplasia, cerebral atrophy, posthemorrhagic hydrocephalus, IUGR, low socioeconomic status, and possibly, low thyroxine levels. Adolescents who were VLBW report satisfactory health; 94% are integrated in regular classes despite neurosensory disabilities (hearing, vision, cerebral palsy, cognition) in 24%.

Predicting Neonatal Mortality.

Birthweight and gestational age have traditionally been used as strong indicators for the risk of neonatal death. Indeed, survival at 22 wk of gestation is close to 0%; with increasing gestational age, survival rates increase to approximately 15% at 23 wk, 56% at 24 wk, and 79% at 25 wk. In addition, birthweight-specific neonatal diseases such as grade IV IVH, severe group B streptococcal pneumonia, and pulmonary hypoplasia also contribute to a poor outcome. Scoring systems that have been developed take into consideration physiologic abnormalities (hypotension-hypertension, acidosis, hypoxia, hypercapnia, anemia, neutropenia), as in the Score for Neonatal Acute Physiology (SNAP), or clinical parameters (gestational age, birthweight, anomalies, acidosis, F_{IO_2}), as in the Clinical Risk Index for Babies (CRIB). CRIB includes 6 parameters collected in the first 12?hr after birth,

and SNAP has 26 variables collected in the first 24?hr. Although these risk scoring systems may provide prognostic information for mortality, they may not be useful for predicting morbidity in survivors. Furthermore, when compared with the clinical judgment of experienced neonatologists (based on birthweight, illness severity, low Apgar score, IUGR, therapeutic requirements), objective risk scores provide similar predictability. Combining a physician's judgment and an objective score may produce a more accurate assessment of the risk of mortality.

Discharge from the Hospital.

Before discharge, a premature infant should be taking all nutrition by nipple, either bottle or breast (Box 86–6). Growth should be occurring at steady increments of approximately 10–30?g/24?hr. Temperature should be stabilized

Box 86.2-6. Recommendations for the Discharge of High-Risk Low-Birthweight Infants

- Resolution of acute life-threatening illnesses
- Ongoing follow-up for chronic but stable problems
  - Bronchopulmonary dysplasia
  - Intraventricular hemorrhage
  - Necrotizing enterocolitis
  - Ventricular septal defect, other cardiac lesions
  - Anemia
  - Retinopathy of prematurity
  - Hearing
  - Apnea
  - Cholestasis
- Stable temperature regulation
- Gaining weight on oral feedings

  - Cholestasis
- Stable temperature regulation
- Gaining weight on oral feedings

  - Breast-feeding
  - Bottle-feeding
  - Gastric tube
- Free of significant apnea; home monitoring for apnea if needed
- Appropriate immunizations and planning for respiratory syncytial virus prophylaxis if indicated
- Hearing screenings
- Ophthalmologic examination if <27 wk or <1,250?g at birth
- Mother's knowledge, skill, confidence documented in
  - Administration of medications (diuretics, methylxanthines, aerosols, etc.)
  - Use of oxygen, apnea monitors, oximeters
  - Nutritional support
    - Timing
    - Volume
    - Mixing concentrated formulas
  - Recognition of illness and deterioration
  - Basic cardiopulmonary resuscitation
  - Infant safety (see Box 86–1)
- Scheduling of referrals
  - Primary care provider
  - Neonatal follow-up clinic
  - Occupational therapy/physical therapy

Neonatal follow-up clinic

Occupational therapy/physical therapy

Imaging (head ultrasound)

Assessment of and solution to social risks (see Box 86–1)

in an open crib. Infants should have had no recent episodes of apnea or bradycardia, and parenteral drug administration should have been discontinued or converted to oral dosing. Stable infants recovering from bronchopulmonary dysplasia may be discharged on a regimen of oxygen given by nasal cannula as long as careful follow-up is arranged with frequent pulse oximetry monitoring and outpatient visits. All infants with a birthweight under 1500?g and those between 1500 and 2000?g with an unstable clinical course requiring oxygen should have an eye examination to screen for retinopathy of prematurity. All LBW infants should have a hearing test. Those who had indwelling umbilical arterial catheters should have their blood pressure measured to check for renal vascular hypertension. The hemoglobin level or hematocrit should be determined to evaluate for possible anemia. If all major medical problems have resolved and the home setting is adequate, premature infants may then be discharged when their weight approaches 1,800–2,100?g; close follow-up plus easy access to health care providers is essential for early discharge protocols. Alternatively, if the medical or social environment is not ideal, high-risk neonates who have been transported to neonatal intensive care units and whose major illness has resolved may be returned to their hospital of birth for an additional period of hospitalization. Standard vaccinations with full doses should commence after discharge or, if in the hospital, with vaccines that do not contain live viruses. For RSV prophylaxis, see Chapter 239 .

Home Care.

While the infant is in the hospital, the mother should be instructed in how to care for the baby after discharge. Ideally, this program should include at least one visit to her home by someone capable of evaluating domestic arrangements and advising about any needed improvements.

86.3 Post-Term Infants

Post-term infants are those born after 42 wk of gestation, as calculated from the mother's last menstrual period, regardless of weight at birth. This designation is often used synonymously with the term “postmature” for infants whose gestation exceeds the normal 280 days by 7 or more days. Approximately 25% of all pregnancies end on or after the 287th day of gestation, 12% on or after the 294th day, and 5% on or after the 301st day. The cause of post-term birth or postmaturity is unknown. Large size of the infant correlates poorly with late delivery but does correlate with large size of either parent, multigravidity, or a prediabetic or diabetic state in the mother.

Clinical Manifestations.

Post-term infants may be clinically indistinguishable from term infants, but some have received the designation postmature because their appearance and behavior suggest those of an infant 1–3 wk of age. These post-term, postmature infants often have increased birthweight and are characterized by the absence of lanugo, decreased or absent vernix caseosa, long nails, abundant scalp hair, white parchment-like or desquamating skin, and increased alertness. If *placental insufficiency* occurs, the amniotic fluid and fetus may be meconium stained, and abnormal fetal heart rates may be observed; the infant may have growth retardation. Although this syndrome is frequently confused with postmaturity, *only about 20% of infants with placental insufficiency syndrome are post-term.* The majority of those affected are term and preterm infants, particularly those SGA who are infants of toxemic mothers, older primigravidas, and women with chronic hypertension. The placentas are often small or poorly attached. This syndrome has been postulated to result from degenerative changes in the placenta that progressively reduce oxygen and nourishment to the fetus.

Infants born post-term in association with presumed placental insufficiency may have various physical signs. Desquamation, long nails, abundant hair, pale skin, alert faces, and loose skin, especially around the thighs and buttocks, give them the appearance of having recently lost weight; meconium-stained nails, skin, vernix, umbilical cord, and placental membranes may also be noted (see Fig. 83–1).

Prognosis.

When delivery is delayed 3 wk or more beyond term, mortality is significantly increased and, in some series, has been approximately three times that of a control group of infants born at term. Mortality has been lowered markedly through improved obstetric management.

Management.

Careful obstetric monitoring, including nonstress testing, biophysical profile, or Doppler velocimetry, usually provides a rational basis for choosing a course of nonintervention, induction of labor, or cesarean section. Induction of labor or cesarean section may be indicated in older primigravidas who go more than 2–4 wk beyond term, particularly if evidence of fetal distress is present. Medical problems in the newborn are treated if they arise.

86.4 Large for Gestational Age

See also Chapter 96 .

Neonatal mortality rates decrease with increasing birthweight until approximately 4,000?g, after which mortality increases. These oversized infants are usually born at term, but preterm infants with weights high for gestational age also have a significantly higher mortality than do infants of the same size born at term; maternal

diabetes and obesity are predisposing factors. Infants who are very large, regardless of their gestational age,

have a higher incidence of birth injuries such as cervical and brachial plexus injuries, phrenic nerve damage with paralysis of the diaphragm, fractured clavicles, cephalohematomas, subdural hematomas, and ecchymoses of the head and face.

The incidence of congenital anomalies, particularly congenital heart disease, is also higher than in term infants of normal weight. Intellectual and developmental retardation is statistically more common in high-birthweight term and preterm infants than in babies of appropriate weight for gestational age.

86.5 Infant Transport

With the advent of regionalized care of high-risk neonates, increasing numbers of sick infants are being transported to neonatal intensive care units in hospitals at which they were not born. Ideally, high-risk mothers should be transported to and their babies delivered at centers where these specialized units are located. Neonatal transport should include consultation about the infant's problem and care before transport, ease of access to the transport team, and transport and stabilization by the team before moving the infant. Securing an airway, providing oxygen, assisting with infant ventilation, providing antimicrobial therapy, maintaining the circulation, providing a warmed environment, and placing intravenous or arterial lines or chest tubes should all be initiated, if indicated, before transport. Infant and maternal records, laboratory reports, and a tube of clotted maternal blood should also be provided. Before departing, the mother should be briefly reassured and allowed to see her stabilized infant, if practical; the father should follow the transport vehicle to the unit. The transport officer or nurse should also call ahead to inform the receiving unit about the nature of the patient's illness.

The transport vehicle should be equipped with appropriate medicines, fluids, oxygen tanks, catheters, chest tubes, endotracheal tubes, laryngoscopes, and an infant warming device. It should be well illuminated and have ample room for emergency procedures and monitoring equipment. With efficient transport and appropriately educated nursing and medical staff at the referring hospitals, the mortality of "outborn" neonates should be no higher than that of those born within the tertiary care center.

Chapter 87 - Clinical Manifestations of Diseases in the Newborn Period

Barbara J. Stoll
Robert M. Kliegman

The wide variety of disorders that affect the newborn originate in utero, during birth, or in the immediate postnatal period. These disorders may represent genetic mutations, chromosomal aberrations, or acquired diseases and injuries. Recognizing disease in newborn infants depends on knowledge of the disorder and evaluation of a limited number of relatively nonspecific clinical signs and symptoms.

Central cyanosis has respiratory, cardiac, central nervous system (CNS), hematologic, and metabolic causes (Box 87–1). Respiratory insufficiency may be due to pulmonary conditions or may be secondary to CNS depression as a result of drugs, intracranial hemorrhage, or anoxia. If it is caused by the former, respirations tend to be rapid and may be accompanied by retraction of the thoracic cage. If it is due to the latter, respirations tend to be irregular and weak and are often slow. Cyanosis unaccompanied by obvious signs of respiratory difficulty suggests cyanotic congenital heart disease or methemoglobinemia. Cyanosis resulting from congenital heart disease may, however, be difficult to clinically distinguish from cyanosis caused by

Box 87-1. Differential Diagnosis of Cyanosis in the Newborn

- Central or peripheral nervous system hypoventilation
  - Birth asphyxia
  - Intracranial hypertension, hemorrhage
  - Oversedation (direct or through maternal route)
  - Diaphragm palsy
  - Neuromuscular diseases
  - Seizures
- Respiratory disease
  - Upper airway
    - Choanal atresia/stenosis
    - Pierre Robin syndrome
    - Intrinsic airway obstruction (laryngeal/bronchial/tracheal stenosis)
    - Extrinsic airway obstruction (bronchogenic cyst, duplication cyst, vascular compression)
  - Lower airway
    - Respiratory distress syndrome
    - Transient tachypnea
    - Meconium aspiration
    - Pneumonia (sepsis)
    - Pneumothorax
    - Congenital diaphragmatic hernia
    - Pulmonary hypoplasia

Pneumothorax

Congenital diaphragmatic hernia

Pulmonary hypoplasia

    - Persistent fetal circulation (persistent pulmonary hypertension of newborn)
- Cardiac right-to-left shunt
  - Abnormal connections (pulmonary blood flow normal or increased)
    - Transposition of great vessels
    - Total anomalous pulmonary venous return
    - Truncus arteriosus
    - Hypoplastic left heart syndrome
    - Single ventricle or tricuspid atresia with large ventricular septal defect but without pulmonic stenosis
  - Obstructed pulmonary blood flow (pulmonary blood flow decreased)
    - Pulmonic atresia with intact ventricular septum
    - Tetralogy of Fallot
    - Critical pulmonic stenosis with patent foramen ovale or atrial septal defect
    - Tricuspid atresia
    - Single ventricle with pulmonic stenosis
    - Ebstein malformation of the tricuspid valve
    - Persistent fetal circulation (persistent pulmonary hypertension of newborn)
- Methemoglobinemia
  - Congenital (hemoglobin M, methemoglobin reductase

hypertension of newborn)

Methemoglobinemia

Congenital (hemoglobin M, methemoglobin reductase deficiency)

Acquired (e.g., nitrates, nitrites)

Inadequate ambient O2 or less O2 delivered than expected (rare)

Disconnection of O2 supply to nasal cannula, head hood

Connection of air, rather than O2, to a mechanical ventilator

Spurious/artifactual

Oximeter artifact (poor contact between probe and skin, poor pulse searching)

Arterial blood gas artifact (contamination with venous blood)

Other

Hypoglycemia

Adrenogenital syndrome

Polycythemia

Blood loss

From Smith F: Cyanosis. In Kliegman: Practical Strategies in Pediatric Diagnosis and Therapy. Philadelphia, WB Saunders, 1996.

respiratory disease. Episodes of cyanosis may also be the initial sign of hypoglycemia, bacteremia, meningitis, shock, or pulmonary hypertension. Peripheral acrocyanosis is common and does not usually warrant concern.

Pallor, in addition to anemia or acute hemorrhage, should suggest hypoxia, asphyxia, hypoglycemia, sepsis, shock, or adrenal failure.

Hypotension in term infants suggests shock from hypovolemia (hemorrhage, dehydration), the systemic inflammatory response syndrome (as a result of bacterial sepsis or intrauterine infection), cardiac dysfunction (left heart obstructive lesions—hypoplastic left heart syndrome, myocarditis, asphyxia-induced myocardial stunning, anomalous coronary artery), pneumothorax, pneumopericardium, pericardial effusion, or metabolic disorders (hypoglycemia, adrenal insufficiency–salt-losing adrenogenital syndrome). Hypotension is a common problem in sick preterm infants and may be due to any of the problems noted in a term infant. It may develop in preterm infants with severe respiratory distress syndrome. Strategies used to support blood pressure include volume expansion (normal saline is equally as effective as 5% albumin), pressors (dopamine, epinephrine), and corticosteroids. Some infants weighing less than 1,000?g do not respond to fluids or inotropic agents but may respond to therapy with hydrocortisone (1–2.5mg/kg q4–6h). Sudden onset of hypotension in a very low birthweight infant suggests pneumothorax, intraventricular hemorrhage, or subcapsular hepatic hematoma.

Convulsions (Chapter 586.5) usually point to a disorder of the CNS and suggest hypoxic-ischemic encephalopathy resulting from asphyxia, intracranial hemorrhage, cerebral anomaly, subdural effusion, meningitis, hypocalcemia, hypoglycemia, infarction, benign familial seizures, and rarely, pyridoxine dependence, hyponatremia, hypernatremia, inborn errors of metabolism, or drug withdrawal. Seizures beginning in the delivery room or shortly thereafter may be due to the unintentional injection of maternal local anesthetic into the fetus. Convulsions may also result from hyponatremia and water intoxication in the infant after the administration of large amounts of hypotonic fluid to the mother shortly before and during delivery.

Convulsions should be distinguished from the jitteriness that may be present in normal newborns, in infants of diabetic mothers, in those who experienced birth asphyxia or drug withdrawal, and in polycythemic neonates. Jitteriness resembling simple tremors may be stopped by holding the infant's extremity; it often depends on sensory stimuli and occurs when the infant is active, and it is not associated with abnormal eye movements. Seizures in premature infants are often subtle and associated with abnormal eye (fluttering, deviation, stare) or facial (chewing, tongue thrusting) movements; the motor component is often that of tonic extension of the limbs, neck, and trunk. Term infants may have focal or multifocal, clonic or myoclonic movements, but they may also have more subtle seizure activity. *Apnea* may be the first manifestation of seizure activity, particularly in a premature infant. Seizures may adversely affect the subsequent neurodevelopmental outcome and even predispose to non-neonatal seizures. Seizures should be treated aggressively.

After severe birth asphyxia, infants may have *motor automatisms* characterized by oral-buccal-lingual movements, rotary limb activities (rowing, pedaling, swimming), tonic posturing, or myoclonus. These motor activities are not usually accompanied by time-synchronized electroencephalographic discharges, may not signify cortical epileptic activity, respond poorly to anticonvulsant therapy, but are associated with a poor prognosis. Such automatisms may represent cortical depression that produces a brainstem release phenomenon or subcortical seizures.

Lethargy may be a manifestation of infection, asphyxia, hypoglycemia, hypercapnia, sedation from maternal analgesia or anesthesia, a cerebral defect, and indeed, almost any severe disease, including inborn errors of metabolism. Lethargy appearing after the 2nd day should, in particular, suggest infection. Lethargy with emesis suggests increased intracranial pressure or an inborn error of metabolism.

Irritability may be a sign of discomfort accompanying intra-abdominal conditions, meningeal irritation, drug withdrawal, infections, congenital glaucoma, or any condition producing pain. As in later infancy, the eardrums should always be examined as a possible source of pain. *Hyperactivity*, especially in a premature infant, may be a sign of hypoxia, pneumothorax, emphysema, hypoglycemia, hypocalcemia, CNS damage, drug withdrawal, neonatal thyrotoxicosis, bronchospasm, esophageal reflux, or discomfort from a cold environment.

The intensive care of neonates involves a number of painful procedures, including heelstick blood sampling, endotracheal intubation and suctioning, mechanical ventilation, and insertion of intravascular catheters. Pain in neonates results in obvious distress and acute physiologic stress responses, and it may have developmental implications for pain in later life.

Pain and discomfort are potentially avoidable problems during the treatment of sick infants. Pre-emptive relief from painful stimuli should be provided before pain or anxiety develops (Chapter 66). The most frequently used drugs are narcotics (morphine, fentanyl) or benzodiazepines (midazolam, lorazepam). Some minor but painful procedures on well neonates have also been managed with oral concentrated (25–50%) sucrose solutions.

Failure to feed well is seen in most sick newborn infants and should always occasion a careful search for infection, a central or peripheral nervous system disorder, intestinal obstruction, and other abnormal conditions.

Fever may be the result of too high an environmental temperature because of weather, overheated nurseries or isolettes/radiant warmers, or too many clothes. It is also noted in “dehydration fever” of newborn infants. If these causes of fever can be eliminated, serious infection (pneumonia, bacteremia, meningitis, and viral infections, particularly herpes simplex or enteroviruses) must be considered, although such infections often occur without provoking a febrile response in newborn infants (see Chapters 161 and 162). An unexplained *fall in body temperature* may accompany infection or other serious disturbances of the circulation or CNS. A sudden servo-controlled increase in isolette temperature to maintain body temperature is a sign of temperature instability and may be associated with sepsis.

Periods of *apnea*, particularly in premature infants, may be associated with various disturbances (see Chapter 90.2). When apnea recurs or when the intervals are longer than 20?sec or are associated with cyanosis or bradycardia, an immediate diagnostic evaluation is needed.

Jaundice during the 1st 24?hr of life warrants diagnostic evaluation and should be considered to be due to hemolysis until proved otherwise. Septicemia and intrauterine infections such as syphilis, cytomegalovirus, and toxoplasmosis should also be considered, especially in infants with an increase in plasma direct-reacting bilirubin.

Jaundice after the 1st 24?hr may be “physiologic” or may be due to septicemia, hemolytic anemia, galactosemia, hepatitis, congenital atresia of the bile ducts, inspissated bile syndrome after erythroblastosis fetalis, syphilis, herpes simplex, or other congenital infections (see Chapter 91.3.3).

Vomiting during the 1st day of life suggests obstruction in the upper digestive tract or increased intracranial pressure. Roentgenographic studies are indicated when obstruction is suspected. Vomiting may also be a nonspecific symptom of an illness such as septicemia. It is a common manifestation of overfeeding or inexperienced feeding technique, pyloric stenosis, milk allergy, duodenal ulcer, stress ulcer, or adrenal insufficiency. Vomitus containing dark blood is usually a sign of a serious illness; the benign possibility of swallowed maternal blood should also be considered. Bile-stained vomitus strongly suggests obstruction below the ampulla of Vater and warrants contrast radiography.

Diarrhea may be a symptom of overfeeding (especially high–caloric density formula), acute gastroenteritis, or malabsorption, or it may be a nonspecific symptom of infection. Diarrhea may occur in conditions accompanied by compromised circulation of part of the intestinal or genital tract, such as mesenteric thrombosis, necrotizing enterocolitis, strangulated hernia, intussusception, and torsion of the ovary or testis.

Abdominal distention, usually a sign of intestinal obstruction or an intra-abdominal mass, may also be seen in infants with enteritis, necrotizing enterocolitis, isolated intestinal perforation, ileus accompanying sepsis, respiratory distress, ascites, or hypokalemia.

TABLE 87-1 -- **Common Life-Threatening Congenital Anomalies**

Name	Manifestations
Choanal atresia	Respiratory distress in delivery room, apnea, unable to pass nasogastric tube through nares. Suspect CHARGE syndrome
Pierre Robin syndrome	Micrognathia, cleft palate, airway obstruction
Diaphragmatic hernia	Scaphoid abdomen, bowel sounds present in chest, respiratory distress

Tracheoesophageal fistula	Polyhydramnios, aspiration pneumonia, excessive salivation, unable to place nasogastric tube in stomach. Suspect VATER syndrome
Intestinal obstruction: volvulus, duodenal atresia, ileal atresia	Polyhydramnios, bile-stained emesis, abdominal distention. Suspect trisomy 21, cystic fibrosis, cocaine
Gastroschisis, omphalocele	Polyhydramnios, intestinal obstruction
Renal agenesis, Potter syndrome	Oligohydramnios, anuria, pulmonary hypoplasia, pneumothorax
Neural tube defects: anencephalus, meningomyelocele	Polyhydramnios, elevated a-fetoprotein, decreased fetal activity
Ductal-dependent congenital heart disease	Cyanosis, hypotension, murmur

CHARGE = Coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies; VATER = vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia.

Failure to move an extremity (pseudoparalysis) suggests fracture, dislocation, or nerve injury. It is also seen in osteomyelitis and other infections that cause pain on movement of the affected part.

CONGENITAL ANOMALIES

Congenital anomalies are a major cause of stillbirths and neonatal deaths, but they are perhaps even more important as causes of acute illness, including metabolic disorders, and long-term morbidity. (Anomalies are discussed in general in Chapters 70 and 97 and specifically in the chapters on the various systems of the body.) Early recognition of anomalies is important for planning care; for some, such as tracheoesophageal fistula, diaphragmatic hernia, choanal atresia, and intestinal obstruction, immediate medical and surgical therapy is essential for survival (Table 87–1). Parents are likely to feel anxious and guilty on learning of the existence of a congenital anomaly and require sensitive counseling.

Chapter 88 - Nervous System Disorders

Barbara J. Stoll
Robert M. Kliegman

Central nervous system (CNS) disorders are important causes of neonatal mortality and both short- and long-term morbidity. The etiology is complex and multifactorial and includes developmental abnormalities that may be genetic and/or environmental, acute problems surrounding delivery, and postnatal

events. Predisposing factors include chronic or acute maternal illness resulting in uteroplacental dysfunction, intrauterine infection, macrosomia/dystocia, prematurity, intrauterine growth restriction, prolonged labor, breech presentation, and acute and often unavoidable emergencies during delivery that result in mechanical and/or hypoxic-ischemic injury.

88.1 The Cranium

Caput succedaneum is a diffuse, sometimes ecchymotic, edematous swelling of the soft tissues of the scalp involving the portion presenting during vertex delivery. It may extend across the midline and across suture lines. The edema disappears within the first few days of life. Analogous swelling, discoloration, and distortion of the face are seen in face presentations. No specific treatment is needed, but if extensive ecchymoses are present, hyperbilirubinemia may develop. *Molding* of the head and overriding of the parietal bones are frequently associated with caput succedaneum and become more evident after the caput has receded, but they disappear during the first weeks of life. Rarely, a hemorrhagic caput may result in shock and require blood transfusion.

Erythema, abrasions, ecchymoses, and *subcutaneous fat necrosis* of facial or scalp soft tissues may be noted after forceps or vacuum-assisted deliveries. Their location depends on the area of application of the forceps. Ecchymoses may be seen after manipulative deliveries and occasionally in premature infants for no discernible reason.

Subconjunctival and retinal hemorrhages are frequent, and *petechiae* of the skin of the head and neck are common. All are probably secondary to a sudden increase in intrathoracic pressure during passage of the chest through the birth canal. Parents should be assured that these hemorrhages are temporary and the result of *normal* events of delivery.

Cephalohematoma (Fig. 88–1) is a subperiosteal hemorrhage, hence always limited to the surface of one cranial bone. No discoloration of the overlying scalp occurs, and swelling is not usually visible until several hours after birth because subperiosteal bleeding is a slow process. An underlying skull fracture, usually linear and not depressed, is occasionally associated with cephalohematoma. Cranial meningocele may be differentiated from cephalohematoma by pulsation, increased pressure on crying, and roentgenographic evidence of a bony defect. Most cephalohematomas are resorbed within 2 wk–3 mo, depending on their size. They may begin to calcify by the end of the 2nd wk. A sensation of central depression suggesting, but not indicative of an underlying fracture or bony defect is usually encountered on palpation of the organized rim of a cephalohematoma. A few remain for years as bony protuberances and are detectable

Figure 88.1-1 Cephalohematoma of the right parietal bone.

roentgenographically as widening of the diploic space; cystlike defects may persist for months or years. Despite these residuals, cephalohematomas require no treatment, although phototherapy may be necessary to ameliorate hyperbilirubinemia. Incision plus drainage is contraindicated because of the risk of introducing infection in a benign condition. A massive cephalohematoma may rarely result in blood loss severe enough to require transfusion. It may also be associated with a skull fracture, coagulopathy, and intracranial hemorrhage.

Fractures of the skull may occur as a result of pressure from forceps or from the maternal symphysis pubis, sacral promontory, or ischial spines. Linear fractures, the most common, cause no symptoms and require no treatment. Depressed fractures are usually indentations of the calvaria similar to a dent in a Ping-Pong ball; they are generally a complication of forceps delivery or fetal compression. Affected infants may be asymptomatic unless they have associated intracranial injury; it is advisable to elevate severe depressions to prevent cortical injury from sustained pressure. Fracture of the occipital bone with separation of the basal and squamous portions almost invariably causes fatal hemorrhage because of disruption of the underlying vascular sinuses. Such fractures may result during breech deliveries from traction on the hyperextended spine of the infant with the head fixed in the maternal pelvis.

88.2 Intracranial-Intraventricular Hemorrhage and Periventricular Leukomalacia

Etiology and Epidemiology.

Intracranial hemorrhage may result from trauma or asphyxia and, rarely, from a primary hemorrhagic disturbance or congenital vascular anomaly. Traumatic epidural, subdural, or subarachnoid hemorrhage is especially likely when the fetal

head is large in proportion to the size of the mother's pelvic outlet, when for other reasons labor is prolonged, in breech or precipitate deliveries, or as a result of mechanical assistance with delivery. Massive subdural hemorrhage, often associated with tears in the tentorium cerebelli or, less frequently, in the falx cerebri, is rare but is encountered more often in full-term than in premature infants. Primary hemorrhagic disturbances and vascular malformations are rare and usually give rise to subarachnoid or intracerebral hemorrhage. Intracranial bleeding may be associated with disseminated intravascular coagulopathy, isoimmune thrombocytopenia, and neonatal vitamin K deficiency (especially in infants born to mothers receiving phenobarbital or phenytoin). Intracranial hemorrhage often involves the ventricles (**intraventricular hemorrhage** [IVH]) of premature infants delivered spontaneously without apparent trauma.

Pathogenesis.

Brain injury is an important problem in very low birthweight (VLBW) preterm infants. The major neuropathologic lesions are IVH and periventricular leukomalacia (PVL). IVH in premature infants occurs in the gelatinous subependymal germinal matrix. This periventricular area is the site of embryonal neurons and fetal glial cells, which migrate outwardly to the cortex. Immature blood vessels in this highly vascular area may be subjected to various forces that, together with poor tissue vascular support, predispose premature infants to IVH. By term, the germinal matrix has become attenuated and the tissue's vascular support has strengthened. *Predisposing factors or events* for IVH include prematurity, respiratory distress syndrome, hypoxic-ischemic or hypotensive injury, reperfusion of damaged vessels, increased or decreased cerebral blood flow, reduced vascular integrity, increased venous pressure, pneumothorax, hypervolemia, and hypertension. These factors result in rupture of the germinal matrix blood vessels. Similar injurious factors (hypoxic-ischemic-hypotensive), venous

obstruction from an IVH, or undetected fetal stress may produce periventricular hemorrhage/necrosis (echodensities). PVL is characterized by focal necrotic lesions in the periventricular white matter and/or more diffuse white matter damage. Cranial ultrasound in the first weeks of life can detect focal echodensities and cystic lesions, but more sophisticated imaging techniques are required to detect diffuse injury.

Understanding of the pathogenesis of PVL is evolving, and both intrauterine and postnatal events are involved. A complex interaction exists between the cerebral vasculature and regulation of cerebral blood flow (both gestational age dependent), disturbances in the oligodendrocyte precursors required for myelination, and maternal/fetal infection and/or inflammation. The risk for PVL increases in infants with IVH and/or ventriculomegaly. Cerebral white matter damage/PVL is responsible for a substantial portion of the adverse neurodevelopment of VLBW preterm infants (cerebral palsy). The possible interaction of various factors in the pathogenesis of white matter damage is shown in Figure 88–2 .

Clinical Manifestations.

The incidence of IVH increases with decreasing birthweight and gestational age: 60–70% of 500–750?g infants and 10–20% of 1,000–1,500?g infants. IVH is rarely present at birth; however, 80–90% of cases occur between birth and the 3rd day of life, 50% occur on the 1st day. Twenty to 40% of cases progress during the 1st wk of life, and delayed hemorrhage may occur in 10–15% of patients after the 1st wk of life. New-onset IVH is rare after the 1st mo of life regardless of birthweight. The most common symptoms are diminished or absent Moro reflex, poor muscle tone, lethargy, apnea, and somnolence. Premature infants with IVH often have a precipitous deterioration on the 2nd or 3rd day of life. Periods of apnea, pallor, or cyanosis; failure to suck well; abnormal eye signs; a high-pitched, shrill cry; muscular twitching, convulsions, decreased

Figure 88.2-2 Schematic of possible associations linking prematurity, intraventricular hemorrhage (IVH), and white matter disorders (WMD). Antenatal factors may represent factors that both lead to prematurity and act as an independent marker of risk for IVH and WMD. Factors that occur as a result of or in association with prematurity may in turn modify the likelihood of having IVH or WMD. IVH in its own right may contribute to WMD. (From Kuban K, Sanocka U, Leviton A, et al: White matter disorders of prematurity: Association with intraventricular hemorrhage and ventriculomegaly. *J Pediatr* 1999;134:539.)

muscle tone, or paralysis; metabolic acidosis; shock; and a decreased hematocrit or failure of the hematocrit to increase after transfusion may be the first indications. The fontanel *may* be tense and bulging. Severe neurologic depression progresses to coma after more severe IVH, with associated hemorrhage in the cerebral cortex and ventricular dilatation. A saltatory pattern consists of symptomatic episodes with intervening asymptomatic periods. In some cases (grade I, II) no clinical manifestations may be seen.

PVL is usually asymptomatic until the neurologic sequelae of white matter damage become apparent in later infancy as spastic motor deficits. PVL may be present at birth but usually occurs later as an early echodense phase (3–10 days of life), followed by the typical echolucent (cystic) phase (14–20 days of life).

Diagnosis.

Intracranial hemorrhage is diagnosed on the basis of the history, clinical manifestations, transfontanel cranial ultrasonography or CT, and knowledge of the birthweight-specific risks of the type of hemorrhage. The diagnosis of *subdural hemorrhage* in a large for gestational age term infant with cephalopelvic disproportion may be delayed 1 mo until the chronic subdural fluid volume expands and produces megalocephaly, frontal bossing, a bulging fontanel, seizures, and anemia. Late occurrence also warrants suspicion of child abuse. Alternatively, a well neonate with a seizure of short duration may have a benign *subarachnoid hemorrhage*.

Although preterm infants with severe IVH manifest rapid shock, mottling, anemia, coma, or a bulging fontanel, many signs of IVH are nonspecific or absent. Therefore, it is recommended that a premature infant be evaluated with routine real-time *cranial ultrasonography* through the anterior fontanel to detect IVH. Infants weighing under 1,500?g (or <30 wk gestational age) are at high risk for IVH and should be examined

within the 1st 7–14 days of life and again at 36–40 wk postmenstrual age. If the 1st scan is abnormal, additional interval examinations are indicated to detect posthemorrhagic hydrocephalus. Ultrasound examination also detects the precystic and cystic symmetric lesions of PVL and the asymmetric intraparenchymal echogenic lesions of cortical hemorrhagic infarction. Furthermore, the delayed development of cortical atrophy, or porencephaly, and the severity, progression, or regression of posthemorrhagic hydrocephalus can be determined by serial ultrasonography. Diffusion-weighted MRI improves the early detection of diffuse PVL/white matter damage and isolated cerebral infarction or stroke.

Three levels of increasing severity of IVH are defined by ultrasound for low-birthweight (LBW) infants: grade I is bleeding confined to the germinal matrix–subependymal region or to less than 10% of the ventricle (?35% of IVH cases), grade II is intraventricular bleeding with 10–50% filling of the ventricle (?40% of IVH cases), and grade III is more than 50% involvement with dilated ventricles (Fig. 88–3). Another classification includes a grade IV IVH, which is similar to grade III plus intraparenchymal hemorrhage. Ventriculomegaly is defined as mild (0.5–1?cm), moderate (1.0–1.5?cm) or severe (>1.5?cm).

CT or MRI is indicated for term infants in whom brain injury is suspected because ultrasound may not reveal intraparenchymal hemorrhage or infarction. Lumbar puncture may be indicated in infants with signs of increased intracranial pressure or a deteriorating clinical condition to identify gross subarachnoid hemorrhage or to rule out the possibility of bacterial meningitis; cerebrospinal fluid usually has elevated protein levels with many red blood cells. Not infrequently, hypoglycorrhachia and mild lymphocytosis can be noted. Because a small amount of bleeding into cerebrospinal fluid often occurs in the course of normal and even cesarean deliveries, small numbers of red blood cells or slight xanthochromia in subarachnoid fluid does not necessarily indicate significant intracranial hemorrhage. Conversely, the subarachnoid fluid may be absolutely clear in

Figure 88.2-3 Grading the severity of germinal matrix intraventricular hemorrhage with parasagittal ultrasound scans. *A*, Grade I. Note the echogenic blood in the germinal matrix *(arrowheads)* just anterior to the anterior tip of the choroid plexus, which (normally) is also echogenic. *B*, Grade II. Note the echogenic blood *(arrowheads)* filling less than 50% of the ventricular area. *C*, Grade III. Note the large blood clot nearly completely filling and distending the entire lateral ventricle. (From Intracranial hemorrhage: Germinal matrix-intraventricular hemorrhage of the premature infant. In Volpe JJ [editor]: *Neurology of the Newborn*, 3rd ed. Philadelphia, WB Saunders, 1995.)

infants with severe subdural or intracerebral hemorrhage and no communication with the subarachnoid space.

Prognosis.

Patients with massive hemorrhage caused by tears of the tentorium or falx cerebri rapidly deteriorate and may die after birth. In utero hemorrhage associated with maternal idiopathic or, more often, fetal alloimmune thrombocytopenia may occur as severe cerebral hemorrhage or a porencephalic cyst after resolution of a fetal cortical hemorrhage.

In most infants with IVH and acute ventricular distention, *posthemorrhagic hydrocephalus* does not develop. Ten to 15% of LBW neonates with IVH have hydrocephalus, which may initially be present without clinical signs such as an enlarging head circumference, apnea, bradycardia, lethargy, a bulging fontanel, or widely split sutures. In infants in whom symptomatic hydrocephalus develops, clinical signs may be delayed 2–4 wk despite progressive ventricular distention and compression (thinning) of the cerebral cortex. Posthemorrhagic hydrocephalus is arrested or regresses in 65% of affected infants.

Progressive hydrocephalus requiring ventricular-peritoneal shunting, intraparenchymal hemorrhage, and extensive PVL are associated with a poor prognosis. IVH with intraparenchymal echodensities larger than 1?cm are associated with high mortality and a high incidence of motor and cognitive deficits. Grade I–II IVH may be due to factors other than severe hypoxia-ischemia and has a lower risk of long-term neurologic sequelae if it is not associated with PVL or intraparenchymal hemorrhage.

Prevention.

The incidence of traumatic intracranial hemorrhage may be reduced by judicious management of cephalopelvic disproportion and operative (forceps, cesarean section) delivery. Fetal or neonatal hemorrhage caused by maternal idiopathic thrombocytopenic purpura or alloimmune thrombocytopenia may be reduced by maternal treatment with steroids, intravenous immunoglobulin, or fetal platelet transfusion and cesarean section. Vitamin K should be given before delivery to all women receiving phenobarbital or phenytoin during the pregnancy. Wide fluctuations in neonatal blood pressure should be avoided.

A single course of antenatal corticosteroids administered to women in preterm labor reduces both IVH (betamethasone and dexamethasone) and PVL (betamethasone only). The safety plus efficacy of multiple courses of antenatal steroids is unknown. Furthermore, the effect of multiple courses of steroids on brain growth and development has raised concern. The prophylactic administration of low-dose indomethacin to VLBW preterm infants reduces the incidence of severe IVH but does not improve the overall outcome.

Treatment.

Although no treatment is available for IVH, it may be associated with other complications that require therapy. Seizures are aggressively treated with anticonvulsant drugs, anemia-shock requires transfusion with packed red blood cells or fresh frozen plasma, and acidosis is treated by the judicious and slow administration of sodium bicarbonate. Neurosurgical placement of an external ventriculostomy catheter may be needed in the early stage of uncontrolled, symptomatic posthemorrhagic hydrocephalus. When a VLBW infant is large enough, a permanent ventricular-peritoneal shunt is placed. Serial lumbar punctures, diuretics, and acetazolamide have no role in the management of posthemorrhagic

hydrocephalus.

Symptomatic subdural hemorrhage in large term infants should be treated by removing the subdural fluid collection with a spinal needle placed through the lateral margin of the anterior fontanel. In addition to birth trauma, child abuse should be suspected in all infants with subdural effusions.

88.3 Spine and Spinal Cord

Injury to the spine/spinal cord is rare but can be devastating. Strong traction exerted when the spine is hyperextended or when the direction of pull is lateral, or forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis, especially when combined with flexion and torsion of the vertical axis, may produce fracture and separation of the vertebrae. Such injuries, rarely diagnosed clinically, are most likely to occur when difficulty is encountered in delivering the shoulders in cephalic presentations and the head in breech presentations.

The injury occurs most commonly at the level of the 4th cervical vertebra with cephalic presentations and the lower cervical–upper thoracic vertebrae with breech presentations. Transection of the cord may occur with or without vertebral fractures; hemorrhage and edema may produce neurologic signs that are indistinguishable from those of transection except that they may not be permanent. Areflexia, loss of sensation, and complete paralysis of voluntary motion occur below the level of injury, although the persistence of a withdrawal reflex mediated through spinal centers distal to the area of injury is frequently misinterpreted as representing voluntary motion. If the injury is severe, the infant, who from birth may be in poor condition because of respiratory depression, shock, or hypothermia, may deteriorate rapidly to death within several hours before any neurologic signs are obvious. Alternatively, the course may be protracted, with symptoms and signs appearing at birth or later in the 1st wk; immobility, flaccidity, and associated brachial plexus injuries may not be recognized for several days. Constipation may also be present. Some infants survive for prolonged periods, their initial flaccidity, immobility, and areflexia being replaced after several weeks or months by rigid flexion of the extremities, increased muscle tone, and spasms. Apnea on day 1 and poor motor recovery by 3 mo are poor prognostic signs.

The differential diagnosis includes amyotonia congenita and myelodysplasia associated with spina bifida occulta. Ultrasonography or MRI confirms the diagnosis. Treatment of the survivors is supportive, including home ventilation; patients often remain permanently disabled. When a fracture or dislocation is causing compression, the prognosis is related to the time elapsed before the compression is relieved.

88.4 Peripheral Nerve Injuries

Brachial Palsy.

Brachial plexus injury is a common problem, with an incidence of 0.6–4.6 per 1,000 live births. Injury to the brachial plexus may cause paralysis of the upper part of the arm with or without paralysis of the forearm or hand or, more commonly, paralysis of the entire arm. These injuries occur in macrosomic infants and when lateral traction is exerted on the head and neck during delivery of the shoulder in a vertex presentation, when the arms are extended over the head in a breech presentation, or when excessive traction is placed on the shoulders. Approximately 45% are associated with shoulder dystocia. In **Erb-Duchenne paralysis**, the injury is limited to the 5th and 6th cervical nerves. The infant loses the power to abduct the arm from the shoulder, rotate the arm externally, and supinate the forearm. The characteristic position consists of adduction and internal rotation of the arm with pronation of the forearm. Power to extend the forearm is retained, but the biceps reflex is absent; the Moro reflex is absent on the affected side (Fig. 88–4). The outer aspect of the arm may have some sensory impairment. Power in the forearm and hand grasp are preserved unless

Figure 88.4-4 Brachial palsy of the left arm (asymmetric Moro reflex).

the lower part of the plexus is also injured; the presence of hand grasp is a favorable prognostic sign. When the injury includes the phrenic nerve, alteration in diaphragmatic excursion may be observed fluoroscopically. **Klumpke paralysis** is a rarer form of brachial palsy; injury to the 7th and 8th cervical nerves and the 1st thoracic nerve produces a paralyzed hand and ipsilateral ptosis and miosis (Horner syndrome) if the sympathetic fibers of the 1st thoracic root are also injured. Mild cases may not be detected immediately after birth. Differentiation must be made from cerebral injury; from fracture, dislocation, or epiphyseal separation of the humerus; and from fracture of the clavicle. MRI demonstrates nerve root rupture or avulsion.

Full recovery occurs in most patients, the prognosis depending on whether the nerve was merely injured or was lacerated. If the paralysis was due to edema and hemorrhage about the nerve fibers, function should return within a few months; if due to laceration, permanent damage may result. Involvement of the deltoid is usually the most serious problem and may result in shoulder drop secondary to muscle atrophy. In general, paralysis of the upper part of the arm has a better prognosis than paralysis of the lower part does.

Treatment consists of partial immobilization and appropriate positioning to prevent the development of contractures. In upper arm paralysis, the arm should be abducted 90 degrees with external rotation at the shoulder, full supination of the forearm, and slight extension at the wrist with the palm turned toward the face. This position may be achieved with a brace or splint during the first 1–2 wk. Immobilization should be intermittent through the day while the infant is asleep and between feedings. In lower arm or hand paralysis, the wrist should be splinted in a neutral position and padding placed in the fist. When the entire arm is paralyzed, the same treatment principles should be followed. Gentle massage and range-of-motion exercises may be started by 7–10 days of age. Infants should be closely monitored with active and passive corrective exercises. If the paralysis persists without improvement for 3–6 mo, neuroplasty, neurolysis, end-to-end anastomosis, and nerve grafting offer hope for partial recovery.

The type of treatment and the prognosis depend on the mechanism of injury and the

number of nerve roots involved. The mildest injury to a peripheral nerve (neurapraxia) is due to edema and heals spontaneously within a few weeks. Axonotmesis is more severe and is due to nerve fiber disruption with an intact myelin sheath; function usually returns in a few months. Total disruption of nerves (neurotmesis) or root avulsion is the most severe, especially if it involves C5–T1; microsurgical repair may be indicated. Fortunately, most (75%) injuries are at the root level C5–C6 and involve neurapraxia and axonotmesis and should heal spontaneously. Botulism toxin may be used to treat biceps-triceps co-contractions.

Phrenic Nerve Paralysis.

Phrenic nerve injury (3rd, 4th, 5th cervical nerves) with diaphragmatic paralysis must be considered

when cyanosis and irregular and labored respirations develop. Such injuries, usually unilateral, are associated with ipsilateral upper brachial palsy. Because breathing is thoracic in type, the abdomen does not bulge with inspiration. Breath sounds are diminished on the affected side. The thrust of the diaphragm, which may often be felt just under the costal margin on the normal side, is absent on the affected side. The *diagnosis* is established by ultrasonography or fluoroscopic examination, which reveals elevation of the diaphragm on the paralyzed side and seesaw movements of the two sides of the diaphragm during respiration.

No specific *treatment* is available; infants should be placed on the involved side and given oxygen if necessary. Initially, intravenous feedings may be needed; later, progressive gavage or oral feeding may be started, depending on the infant's condition. Pulmonary infections are a serious complication. Recovery usually occurs spontaneously by 1–3 mo; rarely, surgical plication of the diaphragm may be indicated.

Facial Nerve Palsy.

Facial palsy is usually a peripheral paralysis that results from pressure over the facial nerve in utero, from efforts during labor, or from forceps use during delivery. Rarely, it may result from nuclear agenesis of the facial nerve. Peripheral paralysis is flaccid and, when complete, involves the entire side of the face, including the forehead. When the infant cries, movement occurs only on the nonparalyzed side of the face, and the mouth is drawn to that side. On the affected side the forehead is smooth, the eye cannot be closed, the nasolabial fold is absent, and the corner of the mouth droops. The forehead wrinkles on the affected side with central paralysis because only the lower two thirds of the face is involved. The infant usually also has other manifestations of intracranial injury, most commonly a 6th nerve palsy. The *prognosis* depends on whether the nerve was injured by pressure or whether the nerve fibers were torn. Improvement occurs within a few weeks in the former instance. Care of the exposed eye is essential. Neuroplasty may be indicated when the paralysis is persistent. Facial palsy may be confused with absence of the depressor muscles of the mouth, which is a benign problem.

Other peripheral nerves are seldom injured in utero or at birth except when they are involved in fractures or hemorrhage.

88.5 Hypoxia-Ischemia

Anoxia is a term used to indicate the consequences of complete lack of oxygen as a result of a number of primary causes. *Hypoxia* refers to an arterial concentration of oxygen that is less than normal, and *ischemia* refers to blood flow to cells or organs that is insufficient to maintain their normal function. *Hypoxic-ischemic encephalopathy* is an important cause of permanent damage to CNS cells that may result in neonatal death or be manifested later as cerebral palsy or mental deficiency. Fifteen to 20% of infants with hypoxic-ischemic encephalopathy die in the neonatal period, and 25–30% of survivors are left with permanent neurodevelopmental abnormalities (cerebral palsy, mental retardation). Prevention is critical because no specific therapy can reverse the CNS injury. Death and disability may sometimes be prevented through symptomatic treatment with oxygen or artificial respiration and correction of the associated multiorgan system dysfunction (Table 88–1). *Asphyxia* is considered in infants with fetal acidosis (pH <7.0), a 5-min Apgar score of 0–3, hypoxic-ischemic encephalopathy (altered tone, depressed level of consciousness, seizures), and other multiorgan system signs (see Table 88–1).

Etiology.

Fetal hypoxia may be caused by (1) inadequate oxygenation of maternal blood as a result of hypoventilation during anesthesia, cyanotic heart disease, respiratory failure, or carbon monoxide poisoning; (2) low maternal blood pressure as a result

TABLE 88.5-1 -- **Effects of Asphyxia**

System	Effect
Central nervous system	Hypoxic-ischemic encephalopathy, infarction, intracranial hemorrhage, seizures, cerebral edema, hypotonia, hypertonia
Cardiovascular	Myocardial ischemia, poor contractility, cardiac stun, tricuspid insufficiency, hypotension
Pulmonary	Pulmonary hypertension, pulmonary hemorrhage, respiratory distress syndrome

Renal	Acute tubular or cortical necrosis
Adrenal	Adrenal hemorrhage
Gastrointestinal	Perforation, ulceration with hemorrhage, necrosis
Metabolic	Inappropriate secretion of antidiuretic hormone, hyponatremia, hypoglycemia, hypocalcemia, myoglobinuria
Integument	Subcutaneous fat necrosis
Hematology	Disseminated intravascular coagulation

of the hypotension that may complicate spinal anesthesia or that may result from compression of the vena cava and aorta by the gravid uterus; (3) inadequate relaxation of the uterus to permit placental filling as a result of uterine tetany caused by the administration of excessive oxytocin; (4) premature separation of the placenta; (5) impedance to the circulation of blood through the umbilical cord as a result of compression or knotting of the cord; (6) uterine vessel vasoconstriction by cocaine; and (7) placental insufficiency from numerous causes, including toxemia and postmaturity.

Placental insufficiency often remains undetected on clinical assessment. Intrauterine growth restriction may develop in chronically hypoxic fetuses without the traditional signs of fetal distress (e.g., bradycardia). Doppler umbilical waveform velocimetry (demonstrating increased fetal vascular resistance, see Fig. 85–3) and cordocentesis (demonstrating fetal hypoxia and lactic acidosis) identify a chronically hypoxic infant. Uterine contractions further reduce umbilical oxygenation and, as a consequence, depress the fetal cardiovascular system and CNS and thereby result in low Apgar scores and postnatal hypoxia in the delivery room.

After birth, hypoxia may be caused by (1) anemia severe enough to lower the oxygen content of the blood to a critical level, as after severe hemorrhage or hemolytic disease; (2) shock severe enough to interfere with the transport of oxygen to vital organs as a result of overwhelming infection, massive blood loss, and intracranial or adrenal hemorrhage; (3) a deficit in arterial oxygen saturation from failure to breathe adequately postnatally because of a cerebral defect, narcosis, or injury; and (4) failure of oxygenation of an adequate amount of blood as a result of severe forms of cyanotic congenital heart disease or pulmonary disease.

Pathophysiology and Pathology.

Within minutes of the onset of total fetal hypoxia, bradycardia, hypotension, decreased cardiac output, and severe metabolic as well as respiratory acidosis occur. The initial circulatory response of the fetus is increased shunting through the ductus venosus, ductus arteriosus, and foramen ovale, with transient maintenance of perfusion of the brain, heart, and adrenals in preference to the lungs (because of pulmonary vasoconstriction), liver, kidneys, and intestine.

The pathology of hypoxia-ischemia is dependent on the affected organ and the severity of the insult. Early congestion, fluid leak from increased capillary permeability, and endothelial cell swelling may then lead to signs of coagulation necrosis and cell death. Congestion and petechiae are seen in the pericardium, pleura, thymus, heart, adrenals, and meninges. Prolonged intrauterine hypoxia may result in PVL and pulmonary arteriole smooth muscle hyperplasia, which predisposes the infant to pulmonary hypertension (Chapter 90.7). If fetal

distress produces gasping, the amniotic fluid contents (meconium, squames, lanugo) are aspirated into the trachea or lungs.

The combination of chronic fetal hypoxia and acute hypoxic-ischemic injury after birth results in gestational age–specific neuropathology. Term infants demonstrate neuronal necrosis of the cortex (later, cortical atrophy) and parasagittal ischemic injury. Preterm infants demonstrate PVL (later, spastic diplegia), status marmoratus of the basal ganglia, and IVH. Term more often than preterm infants have focal or multifocal cortical infarcts that produce focal seizures and hemiplegia. Infarctions are best visualized with contrast CT scanning or rapid diffusion MRI. In addition to focal lesions, CT scanning may demonstrate diffuse decreases in tissue attenuation. Cerebral edema with resultant increased intracranial pressure occurs in some infants who have severe hypoxic-ischemic encephalopathy. Excitatory amino acids may have an important role in the pathogenesis of asphyxial brain injury.

Clinical Manifestations.

Intrauterine growth restriction with increased vascular resistance may be the first indication of fetal hypoxia. During labor, the fetal heart rate slows, and beat-to-beat variability declines. Continuous heart rate recording may reveal a variable or late (type II dips) deceleration pattern (see Fig. 85–4), and fetal scalp blood analysis may show a pH less than 7.20. The acidosis usually has both metabolic and respiratory components. Particularly in infants near term, these signs should lead to the administration of high concentrations of oxygen to the mother and immediate delivery to avoid fetal death or CNS damage.

At *delivery,* the presence of yellow, meconium-stained amniotic fluid is evidence that fetal distress has occurred. At birth, these infants are frequently depressed and fail to breathe spontaneously. During the ensuing hours, they may remain hypotonic or change from hypotonic to hypertonic, or their tone may appear normal (Table 88–2). Pallor, cyanosis, apnea, a slow heart rate, and unresponsiveness to stimulation are also signs of hypoxic-ischemic encephalopathy. Cerebral edema may develop during the next 24?hr and result in profound brainstem depression. During this time, seizure activity may occur, and it may be severe and refractory to the usual doses of anticonvulsants. Phenobarbital, the drug of choice, is given with an intravenous

loading dose (20?mg/kg); additional doses of 10?mg/kg (up to 40–50?mg/kg total) may be needed. Phenytoin (20?mg/kg loading dose) or lorazepam (0.1?mg/kg) may be needed for refractory seizures. Phenobarbital levels should be monitored 24?hr

TABLE 88.5-2 -- **Hypoxic-Ischemic Encephalopathy in Term Infants**

Signs	Stage 1	Stage 2	Stage 3
Level of consciousness	Hyperalert	Lethargic	Stuporous, coma
Muscle tone	Normal	Hypotonic	Flaccid
Posture	Normal	Flexion	Decerebrate
Tendon reflexes/clonus	Hyperactive	Hyperactive	Absent
Myoclonus	Present	Present	Absent
Moro reflex	Strong	Weak	Absent
Pupils	Mydriasis	Miosis	Unequal, poor light reflex
Seizures	None	Common	Decerebration
Electroencephalographic	Normal	Low voltage changing to seizure activity	Burst uppression to isoelectric
Duration	<24?hr if progresses; otherwise, may remain normal	24?hr to 14 days	Days to weeks
Outcome	Good	Variable	Death, severe deficits

Modified from Sarnat H, Sarnat M: Neonatal encephalopathy following fetal distress: A clinical and electroencephalographic study. Arch Neurol 1976; 3:696. Copyright 1976, American Medical Association.

after the loading dose and maintenance therapy (5?mg/kg/24?hr) are begun. Therapeutic phenobarbital levels are 20–40?µg/mL. Though most often a result of the hypoxic-ischemic encephalopathy, seizures in asphyxiated newborns may also be due to hypocalcemia, hypoglycemia, or infection.

In addition to CNS dysfunction, congestive heart failure and cardiogenic shock, persistent pulmonary hypertension (persistent fetal circulation), respiratory distress syndrome, gastrointestinal perforation, hematuria, and acute tubular necrosis are associated with perinatal asphyxia (see Table 88–1).

After delivery, hypoxia is due to respiratory failure and circulatory insufficiency (Chapter 90).

Treatment.

Therapy is supportive and directed at the organ system manifestations. Careful attention to ventilatory status and adequate oxygenation, blood volume, hemodynamic status, acid-base balance, and possible infection is important. No established effective treatment is available for the brain tissue injury, although many drugs (phenobarbital, allopurinol, calcium channel blockers) and procedures (total body or local cranial hypothermia) are under study. Aggressive treatment of seizures is critical and may necessitate continuous electroencephalographic monitoring.

Prognosis.

The outcome of hypoxic-ischemic encephalopathy ranges from complete recovery to death, the prognosis depending on whether the metabolic and cardiopulmonary complications (hypoxia, hypoglycemia, shock) can be treated, the infant's gestational age (outcome is poorest if the infant is preterm), and the severity of the encephalopathy. Severe encephalopathy (stage 3, see Table 88–2), characterized by flaccid coma, apnea, absent oculocephalic reflexes, and refractory seizures, is associated with a poor prognosis. A low Apgar score at 20?min, absence of spontaneous respirations at 20?min of age, and persistence of abnormal neurologic signs at 2 wk of age also predict death or severe cognitive and motor deficits. The combined use of an early electroencephalogram (EEG) and MRI is useful in predicting outcome in term infants with hypoxic-ischemic encephalopathy. Normal MRI and EEG findings are associated with a good recovery, whereas severe MRI and EEG abnormalities predict a poor outcome. All survivors of moderate to severe encephalopathy require comprehensive high-risk medical and developmental follow-up. Early identification of neurodevelopmental problems allows prompt referral for developmental and neurologic care and early intervention services so that the best possible outcome can be achieved.

Brain death after neonatal hypoxic-ischemic encephalopathy is diagnosed by the clinical findings of coma unresponsive to pain, auditory, or visual stimulation; apnea with P_{CO_2} rising from 40 to over 60?mm?Hg; and absent brainstem reflexes (pupil, oculocephalic, oculovestibular, corneal, gag, sucking). These findings must occur in the absence of hypothermia, hypotension, and elevated levels of depressant drugs (e.g., phenobarbital). An absence of cerebral blood flow on radionuclide scans and electrical activity on EEG (electrocerebral silence) is inconsistently observed in clinically brain-dead neonatal infants. Persistence of the clinical criteria for 2 days in term and 3 days in preterm infants predicts brain death in most asphyxiated newborns. Nonetheless, no universal agreement has been reached regarding the definition of neonatal brain death. Consideration of withdrawal of life support should include discussions with the family, the health care team, and if there is disagreement, an ethics committee. The best interest of the infant involves judgments about the benefits and harm of continuing therapy or avoiding ongoing futile therapy.

88.6 Intrauterine Infection (see also Chapter 98)

A variety of agents that infect the mother during pregnancy, labor, and/or delivery can infect the fetus or newborn and cause fetal loss or early neonatal death, multiorgan dysfunction, and/or injury to the developing brain. The most important pathogens are cytomegalovirus (CMV), *Toxoplasma gondii,* herpes simplex virus, *Treponema pallidum,* and rubella virus.

CONGENITAL CYTOMEGALOVIRUS

The greatest risk to the developing fetus is primary CMV infection of the mother during pregnancy. Many women are asymptomatic and the disease may thus go undetected. With primary maternal infection, transmission rates to the fetus range from 24–75%. Like other members of the herpes family, CMV can persist in a latent state after a primary infection. Despite maternal immunity, it can be reactivated during pregnancy and be transmitted to the fetus, or re-infection can occur from a different strain of CMV. The infection is generally less severe in the presence of maternal antibody.

An estimated 0.5–2.5% of all infants are infected with CMV at the time of birth. Approximately 10% of infants with congenital CMV infection in the United States are symptomatic at birth. Less than 10% have generalized *cytomegalic inclusion disease* (CID). CID is characterized by multiorgan involvement, including hepatomegaly, splenomegaly, jaundice, petechiae, microcephaly, chorioretinitis, and fetal growth restriction. About 90% of CMV-infected infants who are symptomatic at birth and 5–15% of those who are asymptomatic will have complications that include sensorineural hearing loss, speech abnormalities, chorioretinitis, optic atrophy, microcephaly, and mental retardation. Prevention efforts have focused on the development of a safe and effective vaccine against CMV. Currently, no treatment has been recommended for maternal infection during pregnancy; however, treatment of symptomatic congenital CMV infection with ganciclovir is being evaluated.

CONGENITAL TOXOPLASMOSIS

Toxoplasmosis during pregnancy can result in fetal infection. The acute signs and symptoms of congenital toxoplasmosis include intrauterine growth restriction, anemia, jaundice, hepatosplenomegaly, intracranial calcifications, hydrocephalus, and microcephaly. Long-term sequelae include visual impairment, blindness, seizures, and mental retardation. The most effective prevention strategy is to avoid risk factors for maternal infection during pregnancy (including contact with infected animals, especially cats, cat feces, or undercooked meat or raw vegetables). Antibiotic treatment during pregnancy (spiramycin for acute maternal infection, pyrimethamine and sulfa for fetal infection) does not appear to reduce the rate of transmission to the fetus, but it does reduce sequelae in infected infants. Postnatal antibiotic treatment of infected infants (pyrimethamine, sulfonamides, and folinic acid) improves the long-term outcome.

HERPES SIMPLEX VIRUS

Both herpes simplex virus types 1 (HSV-1) and 2 (HSV-2) can cause genital infection and can be transmitted from mother to fetus or newborn. HSV infection in the newborn can be acquired in utero (rare), intrapartum (most common), and postnatally. The newborn is at greatest risk for intrapartum transmission if the mother has primary HSV infection at or near the time of delivery (transmission rates of 50% or more with vaginal delivery). Unfortunately, many women are asymptomatic at the time of primary infection. With recurrent maternal infection, intrapartum transmission is reduced to 3–5%, presumably because of pre-existing maternal antibody. Neonatal HSV infection is a life-threatening

illness clinically manifested as isolated CNS disease, disseminated disease with CNS involvement, or isolated skin, eye, and/or mouth infection. CNS damage, including microcephaly, hydranencephaly, and/or meningoencephalitis, can result. Therapy with intravenous acyclovir reduces the risk of death (0% for localized skin disease, 5% for encephalitis, 25% for disseminated disease), but morbidity remains high. Whereas 95% of those with skin disease are normal at 2 yr, only 40% of those surviving encephalitis and 60% of those surviving disseminated disease are normal at 2 yr. Long-term neurologic sequelae include microcephaly, porencephalic cysts, chorioretinitis, blindness, spasticity, and mental retardation. A further reduction in morbidity may result from earlier initiation of antiviral therapy.

CONGENITAL SYPHILIS

The risk of congenital syphilis parallels the rates of syphilis in women of childbearing age. Adequate treatment of syphilis during pregnancy prevents the development of congenital syphilis. Untreated or inadequately treated disease can result in fetal and neonatal disease with multisystem involvement, including anemia, thrombocytopenia, hepatosplenomegaly and jaundice, bone abnormalities, and CNS manifestations. Syphilis is an important preventable cause of stillbirth. CNS sequelae include hydrocephalus, cerebral infarction, meningovasculitis, seizures, and mental retardation. Early identification and treatment of infected infants and diagnosis of CNS syphilis are essential to improve both short- and long-term outcomes. Penicillin is the drug of choice for the treatment of congenital syphilis. Between 1997 and 2000, congenital syphilis rates in the United States declined substantially. With adequate screening and treatment of pregnant women, it is believed that elimination of congenital syphilis in the United States is possible.

CONGENITAL RUBELLA SYNDROME

Maternal infection with rubella in early gestation interferes with critical organ development in the fetus. The resulting defects—cataracts, blindness, deafness, cardiovascular anomalies, microcephaly, and mental retardation—are collectively referred to as congenital rubella syndrome (CRS). The prognosis for infants with severe CRS is poor. For those in whom it is diagnosed during the 1st yr, mortality is

high, and most survivors are seriously impaired. Vaccination against rubella has made CRS increasingly rare in most developed countries. Rubella remains endemic in many developing countries, however, where it is a major preventable cause of hearing impairment, blindness, and adverse neurodevelopmental outcome. Global immunization programs that include rubella vaccination, as well as efforts to identify and respond to rubella outbreaks, are likely to reduce the global burden of CRS.

Chapter 89 - Delivery Room Emergencies

Barbara J. Stoll
Robert M. Kliegman

The most common and important emergency related to newborn infants in the delivery room is failure to initiate and maintain respirations. Less frequent, but of major importance are shock (Chapter 87), severe anemia (Chapter 92.1), plethora (Chapter 92.3), convulsions (Chapter 586.5), and management of life-threatening congenital malformations (Chapter 87).

Respiratory Distress and Failure.

Disorders of respiration in newborn infants can be categorized as either *central nervous system* (CNS) *failure,* representing depression or failure of the respiratory center, or *peripheral respiratory difficulty,* indicating interference with the alveolar exchange of oxygen and carbon dioxide. Cyanosis occurs in both groups (see Table 87–1). Respiratory problems encountered in the delivery room are most frequently those of airway obstruction and depression of the CNS (maternal medications, asphyxia), with an absence of adequate respiratory effort.

Respiratory distress in the presence of good respiratory effort should lead to an immediate consideration of the underlying cause and is an indication for roentgenographic examination of the chest.

If respiratory movements are made with the mouth closed but the infant fails to move air in and out of the lungs, bilateral **choanal atresia** (Chapter 361) or other obstruction of the upper respiratory tract should be suspected. The mouth should be opened and the mouth and posterior of the pharynx cleared of secretions by gentle suction. An oropharyngeal airway should be inserted and the source of the obstruction sought immediately. If effective respiratory flow is not produced by opening the infant's mouth and clearing the airway, laryngoscopy is indicated. With obstructive malformations of the mandible, epiglottis, larynx, or trachea, an endotracheal tube should be inserted; prolonged endotracheal intubation or tracheostomy may be required. Respiratory failure caused by CNS depression or injury may require continuous artificial ventilation with a face mask and bag or through an endotracheal tube.

Hypoplasia of the mandible (Pierre Robin, DiGeorge, and other syndromes) (Chapter 291) with posterior displacement of the tongue may result in symptoms similar to those of choanal atresia and may be temporarily relieved by pulling the tongue forward. A scaphoid abdomen suggests a **diaphragmatic hernia** or **eventration,** as does asymmetry in contour or movement of the chest or a shift of the apical impulse of the heart; these latter manifestations are also compatible with tension pneumothorax. A pneumothorax on the 1st day of life suggests pulmonary hypoplasia, renal malformations, or both.

Pulmonary causes of respiratory difficulty are discussed in Chapter 90 .

Failure to Initiate or Sustain Respiration.

This problem usually originates in the CNS as a result of asphyxia; immaturity in itself is seldom a causative factor except in infants weighing less than 1,000?g. Intrapulmonary problems, such as the pulmonary hypoplasia associated with Potter syndrome, bilateral pleural effusions (hydrops fetalis), and severe intrauterine pneumonia, may at times result in poorly sustained ventilation. The lungs in these infants are very noncompliant, and standard efforts to begin respirations may be inadequate to initiate sufficient ventilation.

Narcosis results from heavy doses of morphine, meperidine (Demerol), fentanyl, barbiturates, or tranquilizers administered to the mother shortly before delivery or from maternal anesthesia given during the 2nd stage of labor. Infants are cyanotic and hypotonic at birth and slow to cry or breathe; when respiration is established, it is extremely slow.

Narcosis should be avoided by using appropriate analgesic and anesthetic practices. Treatment includes initial physical stimulation and securing of a patent airway. If effective ventilation is not initiated, artificial breathing with a mask and bag must be instituted. At the same time, if the depression is due to morphine or its derivatives, naloxone hydrochloride (Narcan), 0.1?mg/kg, should be given by the intravenous, subcutaneous, intratracheal, or intramuscular routes and repeated two to three times if needed. Narcan is contraindicated for maternal opiate addiction because it precipitates acute neonatal withdrawal with severe seizures. Ventilation is essential before and during administration of this antidote. If depression is due to other anesthetics or analgesics, artificial respiration should be continued until the infant is able to sustain ventilation. CNS stimulant drugs should not be used because they are ineffective and may be harmful.

Prenatal or **perinatal hypoxia** of whatever cause, if sufficiently severe, produces brainstem depression and secondary apnea that is unresponsive to sensory stimulation. Death from apnea may be prevented by resuscitation, provided that the basic cause of the hypoxia can be eliminated within a reasonable time while artificial respiration, if necessary, is being carried out. External cardiac massage, correction of acidosis, and circulatory support with drugs may be important adjuncts to ventilation.

Resuscitation.

It is estimated that 5–10% of newborns require some degree of resuscitation at birth. The *goals* of neonatal resuscitation are to prevent the morbidity and mortality associated with hypoxic-ischemic tissue (brain, heart, kidney) injury and to re-establish adequate spontaneous respiration and cardiac output. High-risk situations should be anticipated by the history of the pregnancy, labor, and delivery and by identification of signs of fetal distress. Although the Apgar score is helpful in evaluating patients in need of attention, infants who are born limp, cyanotic, apneic, or pulseless require immediate resuscitation before assignment of the 1-min Apgar score. Rapid and appropriate resuscitative efforts improve the likelihood of preventing brain damage and achieving a successful outcome.

Immediately after birth, an asphyxiated infant should be placed under a radiant heater (to avoid hypothermia), dried, and positioned head down and slightly extended, and the airway should be cleared by suctioning and gentle tactile stimulation provided (slapping the foot, rubbing the back). Simultaneously, the infant's color, heart rate, and respiratory effort should be assessed (Fig. 89–1 (Figure Not Available)).

The steps in neonatal resuscitation follow the ABCs: **A,** *a*nticipate and establish a patent *a*irway by suctioning and, if necessary, performing endotracheal intubation; **B,** initiate *b*reathing by using tactile stimulation or positive-pressure ventilation with a bag and mask or through an endotracheal tube; **C,** maintain the *c*irculation with chest compression and medications, if needed. Steps to follow for immediate neonatal evaluation and resuscitation are outlined in Figure 89–1 (Figure Not Available) (also see Chapter 57.1).

Figure 89-1 (Figure Not Available) Neonatal resuscitation: Decision points and sequential steps. HR = heart rate. (From American Heart Association and American Academy of Pediatrics: *Neonatal Resuscitation Textbook*, 4th ed, 2000, with permission.)

If no respirations are noted or if the heart rate is below 100/min, *positive pressure ventilation* is given through a tightly fitted face mask and bag for 15–30?sec. In infants with severe respiratory depression who do not respond to positive pressure ventilation via bag and mask, endotracheal intubation should be performed. Many recommend early intubation for extremely low-birthweight preterm infants. Guidelines for endotracheal tube size and depth of insertion in infants with different birthweights are shown in Table 89–1 . The optimal concentration of oxygen for newborn resuscitation is unknown; most guidelines recommend 100% oxygen. Although the first breath normally requires pressures as low as 15–20?cm?H_2 O, pressures as high as 30–40?cm?H_2 O may be needed. Subsequent breaths are given at a rate of 40–60/min with a pressure of 15–20?cm?H_2 O. Noncompliant stiff lungs secondary to hyaline membrane disease, congenital pneumonia, or meconium aspiration may require higher pressures. Successful ventilation is determined by adequate chest rise, symmetric breath sounds, improved pink color, heart rate greater than 100/min, spontaneous respirations, presence of end-tidal CO_2 , and improved tone.

If the mother has a history of analgesic narcotic drug administration, naloxone is given while adequate ventilation is maintained. Breathing in the depressed infant should be maintained until a response to naloxone is noted. Continuous observation of the infant is important because repeated doses of naloxone may be needed even after the infant has been transferred to the nursery.

If the heart rate does not improve after 15–30?sec with bag and mask (or endotracheal) ventilation and remains below 60/min or if the rate is less than 80/min and not rising, ventilation is continued and *chest compression* with two fingers is initiated over the lower third of the sternum at a rate of 120/min. The ratio of compressions to ventilation is 3:1. Bradycardia in neonatal infants is usually due to hypoxia resulting from respiratory arrest and often responds rapidly to effective ventilation alone. Persistent bradycardia despite what appears to be adequate resuscitation suggests more severe cardiac compromise or inadequate ventilation technique. Poor response to ventilation may be due to a loosely fitted mask, poor positioning of the endotracheal tube, intra-esophageal intubation, airway obstruction, insufficient pressure, pleural effusions, pneumothorax, excessive air in the stomach, asystole, hypovolemia, diaphragmatic hernia, or prolonged intrauterine asphyxia.

TABLE 89-1 -- **Guidelines for Tracheal Tube Size and Depth of Insertion**

Tube Size (mm ID)	Depth of Insertion from Upper Lip (cm)	Weight (g)	Gestation (wk)
2.5	6.5–7	<1,000	<28
3	7–8	1,000–2,000	28–34
3/3.5	8–9	2,000–3,000	34–38
3.5/4.0	=9	>3,000	>38

ID = internal diameter.

From Kattwinkel J, Niermeyer S, Nadkarni, et al: Resuscitation of the newly born infant: An advisory statement from the Pediatric Working Group of the International Liaison Committee on Resuscitation. Circulation 1999; 99:1927–38. By permission of the American Heart Association, Inc.

Endotracheal intubation should be performed by an experienced person on any infant who does not respond to initial bag and mask ventilation or who was born apneic, pulseless, cyanotic, and limp.

Medications are rarely required but should be administered when the heart rate is less than 60/min after 30?sec of combined ventilation and chest compressions or during asystole. The umbilical vein can generally be readily cannulated and used for immediate administration of medications during neonatal resuscitation (Fig. 89–2 (Figure Not Available)). The endotracheal tube may be used for the administration of epinephrine if intravenous access is not available and/or for naloxone hydrochloride. Epinephrine (0.1–0.3?mL/kg of a 1:10,000 solution, intravenously or intratracheally) is given for asystole or for failure to respond to 30?sec of combined resuscitation. The dose may be repeated every 5?min. If no response is observed, some clinicians recommend using 5 to 10 times the standard dose of epinephrine. Emergency volume expansion is accomplished with 10–20?mL/kg of an isotonic crystalloid solution or O-negative red blood cells (in acute hemorrhage). Sodium bicarbonate (2?mEq/kg, 0.5?mEq/mL of a 4.2% solution) should be given slowly (1?mEq/kg/min) if metabolic acidosis has been documented and the resuscitation is prolonged. Sodium bicarbonate should be given only after effective ventilation has been established because such therapy may increase blood CO_2 and produce respiratory acidosis complicating an existing metabolic acidosis. Restoration of oxygenation

Figure 89-2 (Figure Not Available) Use of the umbilical vein for administration of medications during neonatal resuscitation. (From American Heart Association and American Academy of Pediatrics: *Neonatal Resuscitation Textbook*, 4th ed, 2000, with permision.)

and tissue perfusion is the main treatment of metabolic acidosis associated with asphyxia.

Severe asphyxia may also depress myocardial function and cause cardiogenic shock despite the recovery of heart and respiratory rates. Dopamine or dobutamine administered as a continuous infusion (5–20?µg/kg/min) and fluids should be started after the initial resuscitation effort to improve cardiac output in an infant with poor peripheral perfusion, weak pulses, hypotension, tachycardia, and poor urine output. Epinephrine (0.1–1.0?µg/kg/min) may be indicated for infants in severe shock who do not respond to dopamine or dobutamine (Chapter 57.1).

Less severe degrees of asphyxia can usually be managed by brief periods of bag and mask ventilation. Chest compression and medications are not needed for most neonates who have mild to moderate birth depression. Regardless of the severity of asphyxia or the response to resuscitation, asphyxiated infants should be monitored closely for signs of multiorgan hypoxic-ischemic tissue injury (see Table 88–1).

Shock.

Circulatory insufficiency may be present at birth as a result of severe asphyxia or hemorrhage during gestation, labor, or delivery. Causes of bleeding include hemolysis; placental abruption, previa or tear; traumatic injury to the umbilical cord or internal organs; and intracranial bleeding. Clinical manifestations include signs of respiratory distress, cyanosis, pallor, flaccidity, cold mottled skin, tachycardia or bradycardia, hepatosplenomegaly, and rarely, convulsions. Edema and hepatosplenomegaly may suggest hydrops fetalis or heart failure without shock. Shock from overwhelming infection may also be present after birth.

Supportive treatment with type O Rh-negative blood or normal saline is indicated for hemorrhage or hypovolemia, respectively. Oxygen should be administered and the metabolic acidosis corrected with sodium bicarbonate. Sympathomimetic agents such as dopamine or dobutamine may be needed to support cardiac output and blood pressure. The diagnosis and treatment of erythroblastosis fetalis are discussed in Chapter 92.2 . If infection is present, appropriate antibiotics must be started as soon as possible.

After supportive measures have stabilized the infant's condition, a specific diagnosis should be established and appropriate continuing treatment instituted.

INJURY DURING DELIVERY

Central Nervous System

See Chapter 88 .

Viscera

The **liver** is the only internal organ other than the brain that is injured with any frequency during birth. The damage usually results from pressure on the liver during delivery of the head in breech presentations. Large infant size, intrauterine asphyxia, coagulation disorders, extreme prematurity, and hepatomegaly are contributing factors. Incorrect cardiac massage is a less frequent cause. Hepatic rupture may result in the formation of a subcapsular hematoma, but the capsule may tamponade further bleeding. Infants usually appear normal for the 1st 1–3 days. Nonspecific signs related to loss of blood into the hematoma may appear early and include poor feeding, listlessness, pallor, jaundice, tachypnea, and tachycardia. A mass may be palpable in the right upper quadrant, and the abdomen may appear blue. The hematoma may be large enough to cause anemia. Shock and death may occur if the hematoma ruptures into the peritoneal cavity, where the reduced pressure may allow fresh hemorrhage. Early suspicion by means of ultrasonographic diagnosis and prompt supportive therapy can decrease the mortality associated with this disorder. Surgical repair of a laceration may be required. **Rupture of the spleen** may occur alone or in connection with rupture of the liver. The causes, complications, treatment, and prevention are similar.

Although **adrenal hemorrhage** occurs with some frequency, especially after breech delivery, in infants large for gestational age or infants of diabetic mothers, its cause is undetermined; it may be due to trauma, anoxia, or severe stress, as in overwhelming infection. Ninety per cent are unilateral; 75% are right sided. Calcified central hematomas of the adrenal have been identified roentgenographically or at autopsy in older infants and children, thus suggesting that not all adrenal hemorrhages are immediately fatal. In severe cases, the diagnosis is usually made at postmortem examination. The symptoms are profound shock and cyanosis. A mass may be present in the flank along with overlying skin discoloration; jaundice may also develop. If adrenal hemorrhage is suspected, abdominal ultrasonography may be helpful, and treatment of acute adrenal failure may be indicated (Chapter

569).

Fractures

Clavicle.

This bone is fractured during labor and delivery more frequently than any other bone; it is particularly vulnerable with difficult delivery of the shoulder in vertex presentations and the extended arms in breech deliveries. The infant characteristically does not move the arm freely on the affected side; crepitus and bony irregularity may be palpated, and discoloration is occasionally visible over the fracture site. The Moro reflex is absent on the affected side, and spasm of the sternocleidomastoid muscle with obliteration of the supraclavicular depression at the site of the fracture can be noted. Infants with greenstick fractures may not have any limitation of movement, and the Moro reflex may be present. Fracture of the humerus or brachial palsy may also be responsible for limitation of movement of an arm and absence of a Moro reflex on the affected side. The *prognosis* is excellent. *Treatment,* if any, consists of immobilization of the arm and shoulder on the affected side. A remarkable degree of palpable callus develops at the site within a week and may be the initial evidence of the fracture.

Extremities.

In fractures of the long bones, spontaneous movement of the extremity is usually absent (pseudoparalysis). The Moro reflex is also absent from the involved extremity. Associated nerve involvement may occur. Satisfactory results of treatment of a fractured humerus are obtained with 2–4 wk of immobilization during which the arm is strapped to the chest, a triangular splint and a Velpeau bandage are applied, or a cast is applied. For fracture of the femur, good results are achieved with traction-suspension of both lower extremities, even if the fracture is unilateral; the legs, immobilized in a spica cast, are attached to an overhead frame. Splints are effective for treatment of fractures of the forearm or leg. Healing is usually accompanied by excess callus formation. The *prognosis* is excellent for fractures of the extremities. Fractures in preterm infants may be related to osteopenia (Chapter 95).

Dislocations and **epiphyseal separations** rarely result from birth trauma. The upper femoral epiphysis may be separated by forcible manipulation of the infant's leg as, for example, in breech extraction or after version. The affected leg shows swelling, slight shortening, limitation of active motion, painful passive motion, and external rotation. The diagnosis is established roentgenographically. The prognosis is good for milder injuries, but coxa vara frequently results from extensive displacement.

Nose.

The most prevalent injury to the nose is dislocation of the cartilaginous portion of the septum from the vomerine groove and the columella. The infant may have difficulty nursing and some impairment in nasal respiration. On physical examination, the nares appear asymmetric and the nose flattened. An oral airway

rarely is needed, and surgical consultation should be obtained for definitive treatment.

Chapter 90 - Respiratory Tract Disorders

Barbara J. Stoll
Robert M. Kliegman

Respiratory disorders are the most frequent cause of admission for special care in both term and preterm infants. Signs and symptoms include cyanosis, grunting, nasal flaring, retractions, tachypnea, decreased breath sounds with rales and/or rhonchi, pallor, and apnea. A wide variety of pathologic lesions may be responsible for respiratory disturbances (see Table 87–1 and Box 87–1), including hyaline membrane disease (HMD; respiratory distress syndrome [RDS]), aspiration syndrome, pneumonia, sepsis, congenital heart disease, heart failure, pulmonary hypertension, choanal atresia, hypoglycemia, hypoplasia of the mandible with posterior displacement of the tongue, macroglossia, malformation of the epiglottis, malformation or injury of the larynx, cysts or neoplasms of the larynx or chest, pneumothorax, lobar emphysema, pulmonary agenesis or hypoplasia, congenital pulmonary lymphangiectasis, tracheoesophageal fistula, avulsion of the phrenic nerve, hernia or eventration of the diaphragm, intracranial lesions, neuromuscular disorders, and metabolic disturbances.

It is occasionally difficult to distinguish cardiovascular from respiratory causes or sepsis on the basis of clinical signs alone. Any sign of postnatal respiratory distress is an indication for immediate examination and diagnostic evaluation, including a blood gas determination and roentgenogram of the chest. Timely and appropriate therapy is essential to prevent ongoing injury and improve outcome. As a result of important advances in understanding the pathophysiology of respiratory disease, neonatal and infant deaths from early respiratory disease have declined markedly. The challenge is to continue to improve survival, but also to reduce short- and long-term complications related to early lung disease.

90.1 Transition to Pulmonary Respiration

Successful establishment of adequate lung function at birth is dependent on unobstructed anatomy and maturity of respiratory control. Fluid filling the fetal lungs must be removed, gas containing functional residual capacity (FRC) established and maintained, and a ventilation-perfusion relationship developed that will provide optimal exchange of oxygen and carbon dioxide between alveoli and blood (Chapters 355 , 356 , and 357).

The First Breath.

During vaginal delivery, intermittent compression of the thorax facilitates removal of lung fluid. Surfactant lining the alveoli enhances the aeration of gas-free lungs by reducing surface tension, thereby lowering the pressure required to open alveoli. Nevertheless, the opening pressures required to inflate the airless lungs are higher than those needed at any other period of life; they range from 10–50?cm (usually 10–20?cm) H_2O vs about 4?cm for normal breathing in term infants and adults. The higher pressures needed to initiate respiration are required to overcome the opposing forces of surface tension (particularly in small airways) and the viscosity of liquid remaining in the airways, as well as to introduce about 50?mL of air into the lungs, 20–30?mL of which remains after the first breath to establish FRC. Most of the liquid in the lungs is removed by the pulmonary circulation, which increases many-fold at birth because all the right ventricular output now perfuses the pulmonary vascular bed. The remainder of the fluid is removed by the pulmonary lymphatics, expelled by the infant, swallowed, or aspirated from the oropharynx; removal may be impaired after cesarean section or as a result of endothelial cell damage, hypoalbuminemia, high pulmonary venous pressure, or neonatal sedation.

Stimuli responsible for the first breath are numerous, and their relative importance is uncertain. These stimuli include a decline in P_{O_2} and pH and a rise in P_{CO_2} as a result of interruption of the placental circulation, a redistribution of cardiac output after the umbilical cord is clamped, a decrease in body temperature, and various tactile stimuli.

When compared with term infants, low-birthweight (LBW) infants who have a very compliant chest wall may be at a disadvantage in drawing the first breath. The FRC is least in the most immature infants because of the presence of atelectasis. Abnormalities in the ventilation-perfusion ratio are greater and persist for longer periods, as does gas trapping. LBW infants may have a low Pa_{O_2} (50–60?mm Hg) and an elevated Pa_{CO_2} as a result of atelectasis, intrapulmonary shunting, and hypoventilation. The smallest immature infants have the most profound disturbances, which may resemble RDS.

Breathing Patterns in Newborns.

During sleep in the first months of life, normal full-term infants may have infrequent episodes when regular breathing is interrupted by short pauses. This periodic breathing pattern, which shifts from a regular rhythmicity to cyclic brief episodes of intermittent apnea, is more common in premature infants, who may have apneic pauses of 5–10?sec followed by a burst of rapid respirations at a rate of 50–60/min for 10–15?sec. They rarely have an associated change in color or heart rate, and it often stops without apparent reason. Periodic breathing persists intermittently, usually until premature infants are about 36 wk of gestational age. If an infant is hypoxic, an increase in inspired oxygen concentration often converts periodic to regular breathing. Periodic breathing, a normal characteristic of neonatal respiration, has no prognostic significance.

90.2 Apnea

Apnea is a common problem in preterm infants that may be due to idiopathic apnea of prematurity or an associated illness. In term infants, apnea is always worrisome and demands immediate diagnostic evaluation. Periodic breathing must be distinguished from prolonged apneic pauses because the latter may be associated with serious illnesses. Apnea is a feature of many primary diseases that affect neonates (Table 90–1). These disorders produce apnea by direct depression of the central nervous

TABLE 90.2-1 -- **Potential Causes of Neonatal Apnea and Bradycardia**

Central nervous system	Intraventricular hemorrhage, drugs, seizures, hypoxic injury, herniation, neuromuscular disorders, Leigh syndrome, brainstem infarction or anomalies (e.g., olivopontocerebellar atrophy), after general anesthesia
Respiratory	Pneumonia, obstructive airway lesions, upper airway collapse, atelectasis, extreme prematurity (<1,000?g), laryngeal reflex, phrenic nerve paralysis, severe hyaline membrane disease, pneumothorax, hypoxia
Infectious	Sepsis, necrotizing enterocolitis, meningitis (bacterial, fungal, viral), respiratory syncytial virus
Gastrointestinal	Oral feeding, bowel movement, esophagitis, intestinal perforation
Metabolic	? Glucose, ? calcium, ?/? sodium, ? ammonia, ? organic acids, ? ambient temperature, hypothermia
Cardiovascular	Hypotension, hypertension, heart failure, anemia, hypovolemia, vagal tone
Other	Immaturity of respiratory center, sleep state

system's control of respiration (e.g., hypoglycemia, meningitis, drugs, hemorrhage, seizures), disturbances in oxygen delivery (shock, sepsis, anemia), or ventilation defects (pneumonia, RDS, persistent pulmonary hypertension of the newborn [PPHN], muscle weakness).

Idiopathic apnea of prematurity occurs in the absence of identifiable predisposing diseases. Apnea is a disorder of respiratory control and may be obstructive, central, or mixed. Obstructive apnea (pharyngeal instability, neck flexion, nasal occlusion) is characterized by absent airflow but persistent chest wall motion. Pharyngeal collapse may follow the negative airway pressures generated during inspiration, or it may result from incoordination of the tongue and other upper airway muscles involved in maintaining airway patency. In central apnea, which is caused by decreased central nervous system (CNS) stimuli to respiratory muscles, airflow and chest wall motion are absent. Gestational age is the most important determinant of respiratory control, with the frequency of apnea being inversely related to gestational age. The immaturity of the brainstem respiratory centers is manifested by an attenuated response to carbon dioxide and a paradoxical response to hypoxia that results in apnea rather than hyperventilation. The most common pattern of idiopathic apnea in preterm neonates has a mixed etiology (50–75%), with obstructive apnea preceding (usually) or following central apnea. Short episodes of apnea are usually central, whereas prolonged ones are often mixed.

Apnea is sleep state dependent; the frequency increases during active (rapid eye movement) sleep. Paradoxical chest wall movement (inspiratory abdominal expansion and inward chest wall movement) is common during active sleep and may cause a fall in Pa_{O_2} because of ventilation-perfusion defects. Furthermore, increased negative pressure during paradoxical breathing and inhibition of pharyngeal muscle tone during active sleep may contribute to upper airway collapse and obstructive apnea.

Clinical Manifestations.

The incidence of idiopathic apnea of prematurity varies inversely with gestational age. In preterm infants, it is rare on the 1st day of life; apnea immediately after birth signifies another illness. The onset of idiopathic apnea occurs on the 2nd–7th day of life. The onset of apnea in a previously well premature neonate after the 2nd wk of life or in a term infant at any time is a critical event that warrants immediate investigation. In preterm infants, serious apnea is defined as cessation of breathing for longer than 20?sec, or any duration if accompanied by cyanosis and sinus bradycardia. The incidence of associated bradycardia increases with the length of the preceding apnea and correlates with the severity of hypoxia. Short apnea episodes (10?sec) are rarely associated with bradycardia, whereas longer ones (>20?sec) have a higher incidence of bradycardia. Bradycardia follows the apnea by 1–2?sec in more than 95% of cases; vagal responses and, rarely, heart block are causes of bradycardia without apnea.

Treatment.

Infants at risk for apnea should be monitored with apnea monitors. Gentle *cutaneous stimulation* is often adequate therapy for neonatal infants with mild and intermittent episodes. Infants with recurrent and prolonged apnea require immediate *bag and mask ventilation*. *Oxygen* should be administered judiciously to treat hypoxia. Recurrent apnea of prematurity not due to a precipitating identifiable cause may be treated with *theophylline* or *caffeine*. Methylxanthines enhance ventilation through a central mechanism or by improving diaphragmatic strength. Loading doses of 5?mg/kg of theophylline (orally) or aminophylline (intravenously) should be followed by doses of 1–2?mg/kg given every 6–8?hr by the oral or intravenous routes. Loading doses of 10?mg/kg of caffeine are followed 24?hr later by maintenance doses of 2.5?mg/kg/24?hr qd orally. These doses should be monitored by observation of vital signs, clinical response, and serum drug levels (therapeutic levels: theophylline, 6–10?µg/mL; caffeine, 8–20?µg/mL). *Transfusion of packed red blood cells* to reduce the incidence of idiopathic apnea is reserved for severely anemic infants. The role of gastroesophageal reflux in apnea of prematurity is controversial; indeed, there may be no association. Data do not support the use of antireflux medications to reduce the frequency of apnea in preterm infants.

Nasal continuous positive airway pressure (CPAP, 3–5?cm H_2O) and high-flow nasal cannula (1–2.5?L/min) are effective therapies for mixed or obstructive apnea. Continuous positive pressure splints the upper airway and thereby prevents obstruction. When apnea is due to a precipitating illness, airway stability and oxygenation must be maintained in addition to therapy for the underlying disease.

Prognosis.

Unless severe, recurrent, and refractory to therapy, apnea of prematurity does not alter an infant's prognosis. Associated problems of intraventricular hemorrhage (IVH), bronchopulmonary dysplasia (BPD), and retinopathy of prematurity are critical in determining the prognosis for apneic infants. Apnea of prematurity usually resolves by 36 wk postconceptional age (gestational age at birth plus postnatal age) and does not predict future episodes of sudden infant death syndrome. Some infants with apnea of prematurity are discharged as long as cardiorespiratory monitoring can be performed at home. In the absence of significant events, home monitoring can be safely discontinued at 44–45 wk postconceptional age.

90.3 Hyaline Membrane Disease (Respiratory Distress Syndrome)

Incidence.

HMD occurs primarily in premature infants, and its incidence is inversely proportional

to gestational age and birthweight. It occurs in 60–80% of infants less than 28 wk of gestational age, in 15–30% of those between 32 and 36 wk, in about 5% beyond 37 wk, and rarely at term. An increased frequency is associated with infants of diabetic mothers, delivery before 37 wk gestation, multifetal pregnancies, cesarean section delivery, precipitous delivery, asphyxia, cold stress, and a history of previously affected infants. The incidence is highest in preterm male or white infants. The risk of HMD is reduced in pregnancies with chronic or pregnancy-associated hypertension, maternal opiate addiction, prolonged rupture of membranes, and antenatal corticosteroid use.

Etiology and Pathophysiology.

Surfactant deficiency (decreased production and secretion) is the primary cause of HMD. The failure of FRC to develop and the tendency of affected lungs to become atelectatic correlate with high surface tension and the absence of pulmonary surfactant. The major constituents of surfactant are dipalmitoyl phosphatidylcholine (lecithin), phosphatidylglycerol, apoproteins (surfactant proteins SP-A, -B, -C, -D), and cholesterol (Fig. 90–1). With advancing gestational age, increasing amounts of phospholipids are synthesized and stored in type II alveolar cells (Fig. 90–2). These surface-active agents are released into the alveoli, where they reduce surface tension and help maintain alveolar stability by preventing the collapse of small air spaces at end-expiration. However, the amounts produced or released may be insufficient to meet postnatal demands because of immaturity. Surfactant is present in high concentrations in fetal lung homogenates by 20 wk of gestation, but it does not reach the surface of the lungs until later. It appears in amniotic fluid between 28 and 32 wk. Mature levels of pulmonary surfactant are usually present after 35 wk. Though rare, genetic disorders may contribute to pulmonary outcome. Abnormalities in surfactant protein genes are associated with severe and/or lethal familial respiratory disease.

Synthesis of surfactant depends in part on normal pH, temperature, and perfusion. Asphyxia, hypoxemia, and pulmonary ischemia, particularly in association with hypovolemia,

Figure 90.3-1 Composition of surfactant recovered by alveolar wash. The quantities of the different components are similar for surfactant from the mature lungs of mammals. (From Jobe AH: Fetal lung development, tests for maturation, induction of maturation, and treatment. In Creasy RK, Resnik R [editors]: *Maternal-Fetal Medicine: Principles and Practice*, 3rd ed. Philadelphia, WB Saunders, 1994.)

hypotension, and cold stress, may suppress surfactant synthesis. The epithelial lining of the lungs may also be injured by high oxygen concentrations and the effects of respirator management, thereby resulting in a further reduction in surfactant.

Alveolar atelectasis, hyaline membrane formation, and interstitial edema make the lungs less compliant, so greater pressure is required to expand the small alveoli and airways. In affected infants, the lower part of the chest wall is pulled in as the diaphragm descends, and intrathoracic pressure becomes negative, thus limiting the amount of intrathoracic pressure that can be produced; the result is a tendency for the development of atelectasis. The highly compliant chest wall of preterm infants offers less resistance than that of mature infants to the natural tendency of the lungs to collapse. Thus, at end-expiration, the volume of the thorax and lungs tends to approach residual volume, and atelectasis may develop.

Deficient synthesis or release of surfactant, together with small respiratory units and a compliant chest wall, produces atelectasis and results in perfused, but not ventilated alveoli, which causes hypoxia. Decreased lung compliance, small tidal volumes, increased physiologic dead space, increased work of breathing, and insufficient alveolar ventilation eventually result in hypercapnia. The combination of hypercapnia, hypoxia, and acidosis produces pulmonary arterial vasoconstriction with increased right-to-left shunting through the foramen ovale and ductus arteriosus and within the lung itself. Pulmonary blood flow is reduced, and ischemic injury to the cells producing surfactant and to the vascular bed results in an effusion of proteinaceous material into the alveolar spaces (Fig. 90–3).

Pathology.

The lungs appear deep purplish red and are liver-like in consistency. Microscopically, extensive atelectasis with engorgement of the interalveolar capillaries and lymphatics can be observed. A number of the alveolar ducts, alveoli, and respiratory bronchioles are lined with acidophilic, homogeneous, or granular membranes. Amniotic debris, intra-alveolar hemorrhage, and interstitial emphysema are additional, but inconstant findings; interstitial emphysema may be marked when an infant has been ventilated. The characteristic hyaline membranes are rarely seen in infants dying earlier than 6–8?hr after birth.

Clinical Manifestations.

Signs of HMD usually appear within minutes of birth, although they may not be recognized for several hours in larger premature infants until rapid, shallow respirations have increased to 60/min or greater. A late onset of tachypnea should suggest other conditions. Some patients require resuscitation at birth because of intrapartum asphyxia or initial severe respiratory distress (especially with a birthweight <1,000?g). Characteristically, tachypnea, prominent (often audible) grunting, intercostal and subcostal retractions, nasal flaring, and duskiness are noted. Cyanosis increases and is often relatively unresponsive to oxygen administration. Breath sounds may be normal or diminished with a harsh tubular quality, and on deep inspiration, fine rales may be heard, especially over the lung bases posteriorly. The natural course of untreated HMD is characterized by progressive worsening of cyanosis and dyspnea. If the condition is inadequately treated, blood pressure may fall; fatigue, cyanosis, and pallor increase, and grunting decreases or disappears as the condition worsens. Apnea and irregular respirations occur as infants tire and are ominous signs requiring immediate intervention. Patients may also have a mixed respiratory-metabolic acidosis, edema, ileus, and oliguria. Respiratory failure may occur in infants with rapid progression of the disease. In most cases, the symptoms and signs reach a peak within 3 days, after which improvement is gradual. Improvement is often heralded by spontaneous diuresis and the ability to oxygenate the infant at lower inspired oxygen levels. Death is rare on the 1st day of illness, usually occurs between days 2 and 7, and is associated with alveolar air leaks (interstitial emphysema, pneumothorax) and pulmonary hemorrhage or

IVH. Mortality may be delayed weeks or months if BPD develops in mechanically ventilated infants with severe HMD.

Diagnosis.

The clinical course, a roentgenogram of the chest, and blood gas and acid-base values help establish the clinical diagnosis. Roentgenographically, the lungs may have a characteristic, but not pathognomonic appearance that includes a fine reticular granularity of the parenchyma and air bronchograms, which are

Figure 90.3-3 Contributing factors in the pathogenesis of hyaline membrane disease. The potential "vicious circle" perpetuates hypoxia and pulmonary insufficiency. (From Farrell P, Zachman R: In Quilligan EJ, Kretchmer N [editors]: *Fetal and Maternal Medicine*. New York, John Wiley & Sons, 1980. © 1980. Reprinted by permission of John Wiley & Sons, Inc.)

often more prominent early in the left lower lobe because of superimposition of the cardiac shadow (Fig. 90–4). The initial roentgenogram is occasionally normal, with the typical pattern developing at 6–12?hr. Considerable variation in films may be seen, depending on the phase of respiration and the use of CPAP or positive end-expiratory pressure (PEEP); this variation often results in poor correlation between roentgenograms and the clinical course. Laboratory findings are initially characterized by

Figure 90.3-4 Infant with hyaline membrane disease. Note the granular lungs, air bronchogram, and air-filled esophagus. Anteroposterior *(A)* and lateral *(B)* roentgenograms are needed to distinguish the umbilical artery from the vein catheter and to determine the appropriate level of insertion. The lateral view clearly shows that the catheter has been inserted into an umbilical vein and is lying in the portal system of the liver. A = endotracheal tube; B = umbilical venous catheter at the junction of the umbilical vein, ductus venosus, and portal vein; C = umbilical artery catheter passed up the aorta to T12. (Courtesy of Walter E. Berdon, Babies Hospital, New York City.)

hypoxemia and later by progressive hypoxemia, hypercapnia, and variable metabolic acidosis.

In the *differential diagnosis*, early-onset sepsis may be indistinguishable from HMD. In pneumonia manifested at birth, the chest roentgenogram may be identical to that for HMD. Maternal group B streptococcal colonization, organisms on Gram stain of gastric or tracheal aspirates or a buffy coat smear, and/or the presence of marked neutropenia may suggest the diagnosis of early-onset sepsis. Cyanotic heart disease (e.g., total anomalous pulmonary venous return), persistent pulmonary hypertension, aspiration syndromes, spontaneous pneumothorax, pleural effusions, and congenital anomalies such as cystic adenomatoid malformation, pulmonary lymphangiectasia, diaphragmatic hernia, and lobar emphysema must be considered and require roentgenographic evaluation. Transient tachypnea may be distinguished by its short and mild clinical course. *Congenital alveolar proteinosis* (e.g., congenital surfactant protein B deficiency) is a rare familial disease that is often manifested as severe and lethal RDS in term and premature infants (see Chapter 389).

Prevention.

Most important is prevention of prematurity, including avoidance of unnecessary or poorly timed cesarean section, appropriate management of high-risk pregnancy and labor, and prediction and possible in utero acceleration of pulmonary immaturity (Chapter 85). In timing cesarean section or induction of labor, estimation of fetal head circumference by ultrasonography and determination of the lecithin concentration in amniotic fluid by the lecithin:sphingomyelin ratio (particularly useful with phosphatidylglycerol in diabetic pregnancies) decrease the likelihood of delivering a premature infant. Intrauterine antenatal and intrapartum monitoring may similarly decrease the risk of fetal asphyxia, which is associated with an increased incidence and severity of HMD.

Administration of *betamethasone* to women 48?hr before the delivery of fetuses between 24 and 34 wk of gestation significantly reduces the incidence and the mortality and morbidity of HMD. It is appropriate to administer corticosteroids intramuscularly to all pregnant women who are likely to deliver a fetus in 1 wk that is between 24 and 34 wk gestation. Only one course of therapy is required even if the infant is not delivered until days to weeks later. Prenatal glucocorticoid therapy decreases the severity of RDS and reduces the incidence of other complications of prematurity, such as IVH, patent ductus arteriosus (PDA), pneumothorax, and necrotizing enterocolitis, without affecting neonatal growth, lung mechanics or growth, or the incidence of infection. Prenatal glucocorticoids may act synergistically with postnatal exogenous surfactant therapy. Prenatal dexamethasone may be associated with a higher incidence of periventricular leukomalacia than is the case with betamethasone.

Administration of a first dose of *surfactant* into the trachea of symptomatic premature infants immediately after birth (prophylactic) or during the first few hours of life (early rescue) reduces air leak and mortality from HMD but does not alter the incidence of BPD.

Treatment.

The basic defect requiring treatment is inadequate pulmonary exchange of oxygen and carbon dioxide; metabolic acidosis and circulatory insufficiency are secondary manifestations. Early supportive care of LBW infants, especially in the treatment of acidosis, hypoxia, hypotension (see Chapter 87), and hypothermia, appears to lessen the severity of HMD. Therapy requires careful and frequent monitoring of heart and respiratory rates, Pa_{O_2} , Pa_{CO_2} , pH, bicarbonate, electrolytes, blood glucose, hematocrit, blood pressure, and temperature. Arterial catheterization is frequently necessary. Because most cases of HMD are self-limited, the goal of treatment is to minimize abnormal physiologic variations and superimposed iatrogenic problems. Treatment of these infants is best carried out in a specially staffed and equipped hospital unit, the neonatal intensive care unit (NICU).

The general principles for supportive care of any LBW infant should be adhered to, including gentle handling and minimal disturbance consistent with management. To avoid hypothermia and minimize oxygen consumption, infants should be placed in an isolette or radiant warmer and core temperature maintained between 36.5 and 37°C (Chapters 86 and 87). Calories and fluids should be provided intravenously. For the 1st 24?hr, 10% glucose and water should be infused through a peripheral vein at a rate of 65–75?mL/kg/24?hr. Subsequently, electrolytes should be added and fluid volume increased gradually. Excessive fluids contribute to the development of PDA and BPD.

Warm humidified oxygen should be provided at a concentration initially sufficient to keep arterial levels between 55 and 70?mm Hg (>90% saturation) to maintain normal tissue oxygenation while minimizing the risk of oxygen toxicity. If the Pa_{O_2} cannot be maintained above 50?mm Hg at inspired oxygen concentrations of 60% or greater, applying CPAP at a pressure of 6–10?cm H_2O by nasal prongs is indicated and usually produces a sharp rise in Pa_{O_2} . CPAP prevents collapse of surfactant-deficient alveoli, improves FRC, and improves ventilation-perfusion matching. The amount of CPAP required usually decreases abruptly at about 72?hr of age, and infants can be weaned from CPAP shortly thereafter. If an infant managed by CPAP cannot maintain an arterial oxygen tension above 50?mm Hg while breathing 70–100% oxygen, assisted ventilation is required.

Infants with severe HMD and those with complications that result in persistent apnea require *assisted mechanical ventilation*. Reasonable indications for its use are (1) arterial blood pH less than 7.20, (2) arterial blood P_{CO_2} of 60?mm Hg or higher, (3) arterial blood P_{O_2} of 50?mm Hg or less at oxygen concentrations of 70–100% and CPAP of 8–10?cm H_2O, or (4) persistent apnea. Intermittent positive pressure ventilation delivered by time- cycled, pressure-limited, continuous flow ventilators has been the most common method of conventional ventilation for newborns. Other methods of conventional ventilation include synchronized intermittent mandatory ventilation (the set rate and pressure synchronized with the patient's own breaths), pressure support (the patient triggers each breath and a set pressure is delivered), and volume guarantee (a composite mode in which a specific tidal volume is set and peak pressure is limited). Assisted ventilation for infants with RDS should include PEEP (see Chapter 57.4).

The goals of mechanical ventilation are to improve oxygenation and elimination of carbon dioxide without causing pulmonary barotrauma or oxygen toxicity. Acceptable ranges of blood gas values, after balancing the risks of hypoxia and acidosis against those of mechanical ventilation, are a Pa_{O_2} of 55–70?mm Hg, a P_{CO_2} of 45–55?mm Hg, and a pH of 7.25–7.35. During mechanical ventilation, oxygenation is improved by increasing the F_{IO_2} or mean airway pressure. The latter can be increased by increasing the peak inspiratory pressure, gas flow, the inspiratory:expiratory ratio, or PEEP. Excessive PEEP may impede venous return, thereby reducing cardiac output despite improvement in Pa_{O_2} and thus decreasing oxygen delivery. PEEP levels of 4–6?cm H_2O are usually safe and effective. Carbon dioxide elimination is achieved by increasing the peak inspiratory pressure (tidal volume) or the rate of the ventilator. Many ventilated neonates receive sedation or pain relief with benzodiazepines or opiates (morphine, fentanyl), respectively.

High-frequency ventilation (HFV) was developed to reduce lung injury and/or improve gas exchange in patients with severe respiratory disease. HFV preserves the desired minute ventilation by using smaller tidal volumes and high rates (300–1200 breaths/min or 5–20?Hz). HFV may improve the elimination of carbon dioxide, lower mean airway pressure, and improve oxygenation in patients who do not respond to conventional ventilators and who have severe HMD, interstitial emphysema, many pneumothoraces, or meconium aspiration pneumonia. High-frequency jet ventilation may cause necrotizing tracheal damage, especially in the presence of hypotension or poor humidification, and high-frequency oscillator therapy has been inconsistently associated with an increased risk of air leaks, IVH, and periventricular leukomalacia. Both methods may cause gas trapping. High-frequency oscillation strategies that promote lung recruitment, combined with surfactant therapy, may not reduce the risk for BPD. Complications of endotracheal intubation (plugging of the tube, extubation, subglottic granuloma, and stenosis) and mechanical ventilation (pneumothorax, interstitial emphysema, reduced cardiac output) may be minimized by the interventions of specially trained physicians, nurses, and respiratory therapists in a NICU.

Multidose endotracheal instillation of *exogenous surfactant* to LBW infants requiring 30% oxygen and mechanical ventilation for the treatment (*rescue therapy*) of RDS dramatically improves survival and reduces the incidence of pulmonary air leaks, but it has not consistently reduced the incidence of BPD. Immediate effects include improved alveolar-arterial oxygen gradients, reduced ventilator mean airway pressure, increased pulmonary compliance, and improved appearance of the chest roentgenogram. A number of surfactant preparations have been studied and are widely used, including synthetic surfactants and natural surfactants derived from animal sources. Exosurf is a synthetic surfactant. Natural surfactants include Survanta (bovine), Infasurf (calf), and Curosurf (porcine). Although both synthetic and natural surfactants are effective in the treatment and prevention of RDS, natural surfactants appear to be superior, perhaps because of their surfactant-associated protein content. Natural surfactants have a more rapid onset and are associated with a lower risk of pneumothorax and improved survival. Rapid testing of pulmonary maturity soon after birth by examining tracheal aspirate secretions may reduce the number of unaffected infants treated unnecessarily with surfactant and permit early rescue therapy, usually within the 1st?hr of life.

Treatment (rescue) is initiated as soon as possible in the 1st 24?hr of life. Repeated dosing is given via the endotracheal tube every 6–12?hr for a total of two to four doses, depending on the preparation. Exogenous surfactant should be given by a physician who is qualified in neonatal resuscitation and respiratory management and who is able to care for the infant beyond the 1st?hr of stabilization. Additional on-site staff support required includes nurses and respiratory therapists experienced in the ventilatory management of LBW infants. Appropriate monitoring equipment must also be available (radiology, blood gas laboratory, and pulse oximetry). Furthermore, each institution should have an approved protocol for the administration of surfactant. Complications of surfactant therapy include transient hypoxia and hypotension, blockage of the endotracheal tube, and pulmonary hemorrhage.

Inhaled nitric oxide (iNO) has acutely improved oxygenation, but it may not improve the overall outcome of infants with HMD.

Weaning from the ventilator varies and is based on the mechanics and special features of the ventilator. Once extubated,

---

many infants are transitioned to nasal CPAP to avoid postextubation atelectasis and hypoxia.

Respiratory acidosis may require short-term or prolonged assisted ventilation. In severe respiratory acidosis and hypoxia, treatment with sodium bicarbonate may exacerbate hypercapnia.

Metabolic acidosis in HMD may be a result of perinatal asphyxia and hypotension and is often encountered when an infant has required resuscitation (Chapter 89). Sodium bicarbonate, 1–2?mEq/kg, may be administered over a 15–20?min period through a peripheral or umbilical vein, with the acid-base determination repeated within 30?min, or it may be administered over a period of several hours. Often, sodium bicarbonate is administered on an emergency basis through an umbilical venous catheter. Alkali therapy may result in skin slough from infiltration, increased serum osmolarity, hypernatremia, hypocalcemia, hypokalemia, and liver injury when concentrated solutions are administered rapidly through an umbilical vein catheter wedged in the liver.

Monitoring of *aortic blood pressure* through an umbilical or peripheral arterial catheter or by oscillometric technique may be useful in managing the shocklike state that may occur during the 1st?hr or so after the premature birth of an infant who has been asphyxiated or in whom severe respiratory distress has developed (see Fig. 83–2). Hypotension has been associated with increased CNS morbidity and increased mortality and should be treated with cautious administration of volume (crystalloid) and early use of pressors (usually dopamine). Occasionally, hypotension may be glucocorticoid responsive (see Chapter 87).

Periodic monitoring of Pa_{O_2} , Pa_{CO_2} , and pH is an important part of the management; if assisted ventilation is being used, such monitoring is essential. Blood should be obtained from the umbilical or peripheral artery. Tissue P_{O_2} may also be estimated continuously from transcutaneous electrodes or pulse oximetry (oxygen saturation). Capillary blood samples are of limited value for determining P_{O_2} but may be useful for evaluating P_{CO_2} and pH. Radiopaque umbilical catheters should have their position checked roentgenographically after insertion (see Fig. 90–4). The tip of an umbilical artery catheter should lie just above the bifurcation of the aorta (L3–L5) or above the celiac axis (T6–T10). Preferred sites for peripheral catheters are the radial or posterior tibial arteries. Placement and supervision should be carried out by skilled and experienced personnel. Catheters should be removed as soon as patients no longer have any indication for their continued use—usually when the Pa_{O_2} is stable and the F_{IO_2} is less than 40%.

Because of the difficulty of distinguishing group B streptococcal or other bacterial infections from HMD, empirical antibiotic therapy is indicated until the results of blood cultures are available. Penicillin or ampicillin with kanamycin or gentamicin is suggested; however, the choice of antibiotics is based on the recent pattern of bacterial sensitivity in the hospital where the infant is being treated (Chapter 98).

Complications of HMD and Intensive Care.

The most serious complications of **tracheal intubation** are asphyxia from obstruction of the tube, cardiac arrest during intubation or suctioning, and the subsequent development of subglottic stenosis. Other complications include bleeding from trauma during intubation, posterior pharyngeal pseudodiverticula, difficult extubation requiring tracheostomy, ulceration of the nares because of pressure from the tube, permanent narrowing of the nostril as a result of tissue damage and scarring from irritation or infection around the tube, erosion of the palate, avulsion of a vocal cord, laryngeal ulcer, papilloma of a vocal cord, and persistent hoarseness, stridor, or edema of the larynx.

Measures to reduce the incidence of these complications include skillful intubation, adequate securing of the tube, use of polyvinyl endotracheal tubes, use of the smallest size tube sufficient to reduce local ischemia and pressure necrosis, avoidance of frequent changes and motion of the tube in situ, avoidance of too frequent or vigorous suctioning, and prevention of infection through meticulous cleanliness and frequent sterilization of all apparatus attached to or passed through the tube. The personnel inserting and caring for the endotracheal tube should be experienced and skilled.

Risks associated with **umbilical arterial catheterization** include vascular embolization, thrombosis, spasm, and perforation; ischemic or chemical necrosis of abdominal viscera; infection; accidental hemorrhage; and impaired circulation to a leg with subsequent gangrene. Although the reported incidence of thrombotic complications varies from 1–23% at necropsy, aortography has demonstrated that clots form in or about the tips of 95% of catheters placed in an umbilical artery. Aortic ultrasonography can also be used to investigate the presence of thrombosis. The risk of a serious clinical complication resulting from umbilical catheterization is probably between 2 and 5%.

Transient blanching of the leg may occur during catheterization of the umbilical

artery. It is usually due to reflex arterial spasm, the incidence of which is lessened by using the smallest available catheter, particularly in very small infants. The catheter should be removed immediately; catheterization of the other artery may then be attempted. Persistent spasm after removal of the catheter may be relieved by topical nitroglycerin applied over the femoral artery or, rarely, by warming the opposite leg. Blood sampling from a radial artery may similarly result in spasm or thrombosis, and the same treatment is indicated. Intermittent severe spasm or unrelieved spasm may respond to the cautious use of topical nitroglycerin or local infusion of tolazoline (Priscoline), 1–2?mg injected intra-arterially over a 5?min period. Accidentally lodging the catheter in a smaller artery, either blocking it completely or causing unrecognized local vascular spasm, may result in gangrene of the organ or area supplied by the vessel. To prevent this complication, the catheter should be removed promptly if blood cannot be withdrawn from it.

Serious hemorrhage on removal of the catheter is rare. Thrombi may form in the artery or in the catheter, the incidence of which can be lowered by using a smooth-tipped catheter with a hole only at its end, by rinsing the catheter with a small amount of saline solution containing heparin, or by continuously infusing a solution containing 1–5?U/mL of heparin. The risk of thrombus formation with potential vascular occlusion can also be reduced by removing the catheter when early signs of thrombosis are noted, such as narrowing of pulse pressure and disappearance of the dicrotic notch. Some prefer to use the umbilical artery for blood sampling only and leave the catheter filled with heparinized saline between samplings. *Renovascular hypertension* may occur days to weeks after umbilical arterial catheterization in a small number of neonates.

Umbilical vein catheterization is associated with many of the same risks as umbilical artery catheterization. An additional risk is cardiac perforation and pericardial tamponade if the catheter is placed in the right atrium; portal hypertension can subsequently develop from portal vein thrombosis, especially in the presence of omphalitis.

Extrapulmonary extravasation of air is another complication of the management of HMD (Chapter 90.8).

Some neonates with HMD may have clinically significant shunting through a **PDA**, the delayed closure being due to associated hypoxia, acidosis, increased pulmonary pressure secondary to vasoconstriction, systemic hypotension, immaturity, and local release of prostaglandins, which dilate the ductus. There appears to be a link between early adrenal insufficiency, ductal patency, airway inflammation, and the development of BPD. Shunting through the PDA may initially be bidirectional or right to left. As HMD resolves, pulmonary vascular resistance

decreases, and left-to-right shunting may occur and lead to left ventricular volume overload and pulmonary edema. Manifestations of PDA may include (1) persistent apnea for unexplained reasons in an infant recovering from HMD; (2) an active heaving precordium, bounding peripheral pulses, wide pulse pressure, and a systolic or to-and-fro murmur; (3) carbon dioxide retention; (4) increasing oxygen dependence; (5) roentgenographic evidence of cardiomegaly and increased pulmonary vascular markings; and (6) hepatomegaly. The diagnosis is confirmed by echocardiographic visualization of a PDA with Doppler flow evidence of left-to-right shunting. Many infants respond to general supportive measures, including diuretics and fluid restriction. In patients in whom spontaneous closure does not occur and deterioration progresses despite supportive and cardiotonic treatment, intravenous indomethacin, 0.2?mg/kg at 12–24?hr intervals for three doses, may induce pharmacologic closure by inhibiting prostaglandin synthesis; repeated courses may be needed. Prophylactic low-dose indomethacin reduces the incidence of both IVH and PDA and improves the rate of permanent ductal closure, but it does not improve the long-term prognosis. Contraindications to indomethacin include thrombocytopenia (<50,000/mm^3), bleeding disorders, oliguria (<1?mL/kg/hr), necrotizing enterocolitis, and an elevated plasma creatinine level (>1.8?mg/dL). Ibuprofen (initial dose of 10?mg/kg, followed at 24?hr intervals by two doses of 5?mg/kg), unlike indomethacin, does not reduce cerebral, mesenteric, or renal blood flow and may be equally effective in closing a PDA. Ibuprofen has rarely been associated with pulmonary hypertension. Indications for surgical closure are failure to close the ductus after one to two courses of drug therapy along with persistent heart failure and ventilator dependence.

BPD is a result of lung injury in infants requiring mechanical ventilation and supplemental oxygen. The BPD described in 1967 by Northway, in an era before the widespread use of antenatal steroids and postnatal surfactant, was a disease of large preterm infants with severe lung injury resulting from mechanical ventilation and oxygen. Today, BPD is a disease primarily of extremely low-birthweight (ELBW) infants, usually under 1,000?g at birth, many of whom have little or no lung disease at birth but in whom progressive disease develops over time.

A consistent pathologic finding in these infants is decreased alveolarization, decreased septation, and minimal airway disease, all of which suggest arrest in lung development. The lung injury is due to an interaction of multiple factors. RDS is a disease of progressive alveolar collapse. Atelectasis (which is affected by insufficient PEEP), together with ventilator-induced increased lung volume and regional overdistention (volutrauma), promotes injury. Oxygen induces injury by producing free radicals that cannot be metabolized by the immature antioxidant systems of ELBW neonates. Mechanical ventilation and/or oxygen injure the preterm lung by affecting alveolar and vascular development. Moreover, inflammation (measured by circulating neutrophils, neutrophils and macrophages in alveolar fluid, and pro-inflammatory cytokines) contributes to the progression of lung injury. Potential inflammatory or tissue metabolic product markers for BPD have been identified in blood, urine, and tracheal aspirates. Several clinical factors, including immaturity, infection, symptomatic PDA, and malnutrition, contribute to the development of BPD.

BPD is usually defined as a need for supplemental oxygen at 36 wk after conception. Another definition of BPD is based on the severity of disease (Table 90–2). Studies to define BPD based on the physiologic need for oxygen are ongoing. The occurrence of BPD is inversely related to gestational age. Instead of showing improvement on the 3rd–4th day, consistent with the natural course of RDS, some infants who have been maintained by mechanical ventilation with increased concentrations of oxygen show a worsening of their pulmonary condition. The respiratory distress persists and is characterized by hypoxia, hypercapnia, oxygen dependence, and in severe cases, the development of right-sided heart failure. The

chest roentgenogram is described as gradually changing from a picture of almost complete opacification with air bronchograms and interstitial emphysema to one of small, round, radiolucent areas alternating with areas of irregular density resembling a sponge (Fig. 90–5). Histologic study at this stage (10–20 days after beginning oxygen therapy) shows less evidence of hyaline membrane formation, progressive alveolar coalescence with atelectasis of the surrounding alveoli, interstitial edema, coarse focal thickening of the basement membrane, and widespread bronchial and bronchiolar mucosal metaplasia and hyperplasia. These findings correspond to a severe maldistribution of ventilation.

Most surviving neonates with persistent roentgenographic changes recover by 6–12 mo, but some require prolonged hospitalization and may have respiratory symptoms persisting through childhood (bronchospasm). Right-sided heart failure and acquired viral necrotizing bronchiolitis (respiratory syncytial virus) are major causes of death in infancy. Pathologic examination reveals cardiac enlargement and pulmonary changes consisting of focal areas of emphysematous alveoli with hypertrophy

TABLE 90.3-2 -- **Definition of Bronchopulmonary Dysplasia: Diagnostic Criteria**

Gestational Age	**<32 wk**	**= 32 wk**
Time point of assessment	36 wk PMA or discharge home, whichever comes first	>28 days' but <56 days' postnatal age or discharge home, whichever comes first. Treatment with >21% oxygen for at least 28 days **plus**
	Treatment with >21% oxygen for at least 28 days **plus**	
Mild BPD	Breathing room air at 36 wk PMA or discharge, whichever comes first	Breathing room air by 56 days postnatal age or discharge, whichever comes first
Moderate BPD	Need[*] <30% oxygen at 36 wk PMA or discharge, whichever comes first	Need[*] for <30% oxygen at 56 days' postnatal age or discharge, whichever comes first
Severe BPD	Need[*] for =30% oxygen and/or positive pressure (PPV or NCPAP) at 36 wk PMA or discharge, whichever comes first	Need[*] for =30% oxygen and/or positive pressure (PPV or NCPAP) at 56 days' postnatal age or discharge, whichever comes first

BPD usually develops in neonates being treated with oxygen and PPV for respiratory failure, most commonly respiratory distress syndrome. Persistence of the clinical features of respiratory disease (tachypnea, retractions, crackles) is considered common to the broad description of BPD and has not been included in the diagnostic criteria describing the severity of BPD. Infants treated with greater than 21% oxygen and/or positive pressure for nonrespiratory disease (e.g., central apnea or diaphragmatic paralysis) do not have BPD unless parenchymal lung disease also develops and they have clinical features of respiratory distress. A day of treatment with greater than 21% oxygen means that the infant received greater than 21% oxygen for more than 12?hr on that day. Treatment with greaterthan 21% oxygen and/or positive pressure at 36 wk PMA or at 56 days' postnatal age or discharge should not reflect an “acute” event, but should rather reflect the infant's usual daily therapy for several days preceding and following 36 wk PMA, 56 days' postnatal age, or discharge.

PMA = postmenstrual age; BPD = bronchopulmonary dysplasia; PPV = positive pressure ventilation; NCPAP = nasal continuous positive airway pressure.

[*] A physiologic test confirming that the oxygen requirement at the assessment time point remains to be defined. This assessment may include a pulse oximetry saturation range.

Figure 90.3-5 Pulmonary changes in infants treated with prolonged, intermittent positive pressure breathing with air containing 80–100% oxygen in the immediate postnatal period for the clinical syndrome of hyaline membrane disease. *A*, A 5-day-old infant with nearly complete opacification of the lungs. *B*, A 13-day-old infant withl “bubbly lungs” simulating the roentgenographic appearance of the Wilson-Mikity syndrome. *C*, A 7-mo-old infant with irregular, dense strands in both lungs, hyperinflation, and cardiomegaly suggestive of chronic lung disease. *D*, Large right ventricle and a cobbly, irregularly aerated lung of an infant who died at 11 mo of age. This infant also had a patent ductus arteriosus. (From Northway WH Jr, Rosan RC, Porter DY: Pulmonary disease following respirator therapy of hyaline-membrane disease. *N Engl J Med* 1967;276:357.)

of the peribronchial smooth muscle of the tributary bronchioles, some perimucosal fibrosis and widespread metaplasia of the bronchiolar mucosa, thickening of basement membranes, and separation of the capillaries from the alveolar epithelial cells.

Infants at risk for BPD usually have severe respiratory distress requiring prolonged periods of mechanical ventilation and oxygen therapy. Additional associations include the presence of interstitial emphysema, lower gestational age, male sex, low P_{CO_2} during the treatment of HMD, PDA, high peak inspiratory pressure, increased airway resistance in the 1st wk of life, increased pulmonary artery pressure, and possibly a family history of asthma. In some very low birthweight infants without

HMD who require mechanical ventilation for apnea or respiratory insufficiency, BPD that does not follow the classic pattern may develop. Vitamin A supplementation (5,000?IU intramuscularly three times per week for 4 wk) in ELBW infants reduces the risk of BPD (1 case prevented for every 14–15 treated).

Severe BPD requires continued mechanical ventilation until weaning from the respirator becomes possible. Acceptable blood gas concentrations for a patient with severe BPD include a P_{CO_2} of 50–70?mm Hg (if pH > 7.30) and a Pa_{O_2} of 55–60?mm Hg with an oxygen saturation of 95% or higher. Lower levels of Pa_{O_2} may exacerbate pulmonary hypertension, produce cor pulmonale, and inhibit growth. Airway obstruction in BPD may be due to mucus and edema production, bronchospasm, and collapse of acquired tracheomalacia. These events may contribute to "blue spells." Alternatively, blue spells may be due to acute cor pulmonale or myocardial ischemia.

Treatment of BPD includes nutritional support, fluid restriction, drug therapy, maintenance of adequate oxygenation, and prompt treatment of infection. Growth must be monitored because recovery is dependent on the growth of lung tissue and remodeling of the pulmonary vascular bed. Nutritional supplementation to provide added calories (24–30 calories/30?mL formula) and protein (3–3.5?g/kg/24?hr) is needed for growth. Diuretic therapy results in a short-term improvement in lung mechanics and may result in decreased oxygen and ventilatory requirements. Furosemide (1?mg/kg/dose intravenously twice daily [bid] or 2?mg/kg/dose orally bid) given daily or every other day and hydrochlorothiazide alone or in combination with potassium chloride, if needed, or spironolactone are commonly used drugs. Bronchodilators improve lung mechanics by decreasing airway resistance. Both inhaled $ß_2$ -adrenergic agents and systemic aminophylline or theophylline (at serum levels of 12–15?mg/L) are used. Adequate oxygenation (pulse oximeter =95%) is essential to prevent or treat cor pulmonale and to promote optimal growth and neurodevelopmental outcome. In severe cases, iNO may improve oxygenation. Mortality in infants with BPD ranges from 10–25% and is highest in infants who remain ventilator dependent for over 6 mo. Cardiorespiratory failure (associated with cor pulmonale) and infection (respiratory syncytial virus) are common causes of death.

Postnatal dexamethasone preventive therapy reduces the time to extubation and may decrease the risk of BPD. However, such therapy is associated with substantial short- and long-term risks, including hypertension, hyperglycemia, gastrointestinal bleeding and perforation, hypertrophic cardiomyopathy, sepsis, and poor weight gain and head growth. Survival is not improved, and infants who have been treated with dexamethasone have an apparent increase in neurodevelopmental delay and cerebral palsy. Therefore, the routine use of dexamethasone for the prevention or treatment of BPD is not recommended.

Complications of BPD include growth failure, psychomotor retardation, and parental stress, as well as sequelae of therapy such as nephrolithiasis (from diuretics and total intravenous alimentation), osteopenia, and subglottic stenosis, which may require tracheotomy or an anterior cricoid-split procedure to relieve upper airway obstruction.

Patients with BPD often go home on a regimen of oxygen, diuretics, and bronchodilator therapy. Prevention of sleep-associated hypoxia improves growth, as does hypercaloric formula. The long-term *prognosis* is good for infants who have been weaned from oxygen before discharge from the NICU. Prolonged ventilation, IVH, pulmonary hypertension, cor pulmonale, and oxygen dependence beyond 1 yr of life are poor prognostic signs. Airway obstruction and hyperactivity and hyperinflation may be demonstrated in some adolescents.

Prognosis.

Early provision of intensive observation and care of high-risk newborn infants can significantly reduce the morbidity and mortality associated with HMD and other acute neonatal illnesses. Antenatal steroids, postnatal surfactant use, improved modes of ventilation, and supportive NICUs have resulted in low mortality from HMD (?10%). Mortality increases with decreasing gestational age. Good results depend on the availability of experienced and skilled personnel, specially designed and organized regional hospital units, proper equipment, and lack of complications such as severe asphyxia, intracranial hemorrhage, or irremediable congenital malformation. Surfactant therapy has reduced mortality from HMD approximately 40%; the incidence of BPD has not been measurably affected.

The overall mortality in LBW infants referred to intensive care centers is steadily declining (see Chapter 86.2). Although 85–90% of all infants surviving HMD after requiring ventilatory support with respirators are normal, the outlook is much better for those weighing above 1,500?g. The long-term prognosis for normal pulmonary function in most infants surviving HMD is excellent. However, survivors of severe neonatal respiratory failure may have significant pulmonary and neurodevelopmental impairment.

90.4 Transient Tachypnea of the Newborn

Transient tachypnea, occasionally called **respiratory distress syndrome type II,** usually follows uneventful normal preterm or term vaginal delivery or cesarean delivery. It may be characterized by the early onset of tachypnea, sometimes with retractions, or expiratory grunting and, occasionally, cyanosis that is relieved by minimal oxygen (<40%). Patients usually recover rapidly within 3 days, although they may rarely appear severely ill and have a more protracted course. The lungs are generally clear without rales or rhonchi, and the chest roentgenogram shows prominent pulmonary vascular markings, fluid lines in the fissures, overaeration, flat diaphragms, and, occasionally, pleural fluid. Hypoxemia, hypercapnia, and acidosis are uncommon. Distinguishing the disease from HMD may be difficult; the distinctive features of transient tachypnea are sudden recovery of the infant and the absence of a roentgenographic reticulogranular pattern or air bronchograms. The syndrome is believed to be secondary to slow absorption of fetal lung fluid resulting in decreased pulmonary compliance and tidal volume and increased dead space.

90.5 Aspiration of Foreign Material (Fetal Aspiration Syndrome, Aspiration Pneumonia)

During prolonged labor and difficult deliveries, infants often initiate vigorous respiratory movements in utero because of interference with the supply of oxygen through the placenta. Under such circumstances, the infant may aspirate amniotic fluid containing vernix caseosa, epithelial cells, meconium, or material from the birth canal, which may block the smallest airways and interfere with alveolar exchange of oxygen and carbon dioxide. Pathogenic bacteria may accompany the aspirated material, and pneumonia may ensue, but even in noninfected cases, respiratory distress accompanied by roentgenographic evidence of aspiration is seen (Fig. 90–6).

Pulmonary aspiration may also occur in newborn infants as a result of tracheoesophageal fistula, esophageal and duodenal obstruction, gastroesophageal reflux, improper feeding practices, and administration of depressant medicines.

The contents of the stomach should be aspirated through a soft catheter just before surgery or other procedures that require anesthesia or significantly disturb an infant. Once aspiration has occurred, treatment consists of general and respiratory

Figure 90.5-6 Fetal aspiration syndrome (aspiration pneumonia). Note the coarsely granular pattern with irregular aeration typical of fetal distress from the aspiration of material contained in amniotic fluid, such as vernix caseosa, epithelial cells, and meconium.

support and treatment of pneumonia (Chapters 90.3 and 380). **REFERENCES**

Goodwin SR, Graves SA, Haberkern CM: Aspiration in intubated premature infants. *Pediatrics* 1985;75:85.

90.6 Meconium Aspiration

Meconium-stained amniotic fluid is found in 10–15% of births and usually occurs in term or post-term infants. Meconium aspiration pneumonia develops in 5% of such infants; 30% of them require mechanical ventilation, and 3–5% expire. Usually but not invariably, fetal distress and hypoxia occur with passage of meconium into amniotic fluid. These infants are meconium stained and may be depressed and require resuscitation at birth. The pathophysiology is noted in Figure 90–7 .

Clinical Manifestations.

Either in utero or more often with the first breath, thick, particulate meconium is aspirated into the lungs. The resulting small airway obstruction may produce respiratory distress within the first hours, with tachypnea, retractions, grunting, and cyanosis observed in severely affected infants. Partial obstruction of some airways may lead to pneumothorax or pneumomediastinum, or both. Prompt treatment may delay the onset of respiratory distress, which may consist of only tachypnea without retractions. Overdistention of the chest may be prominent. The condition usually improves within 72?hr, but when its course requires assisted ventilation, it may be severe with a high risk for mortality. Tachypnea may persist for many days or even several weeks. The typical chest roentgenogram is

Figure 90.6-7 Pathophysiology of meconium passage and the meconium aspiration syndrome. (From Wiswell TE, Bent RC: Meconium staining and the meconium aspiration syndrome. *Pediatr Clin North Am* 1993;40:955.)

characterized by patchy infiltrates, coarse streaking of both lung fields, increased anteroposterior diameter, and flattening of the diaphragm. A normal chest roentgenogram in an infant with severe hypoxia and no cardiac malformation suggests the diagnosis of pulmonary hypertension (Chapter 90.7). Arterial P_{O_2} may be low in either disease, and if hypoxia has occurred, metabolic acidosis is usually present.

Prevention.

The risk of meconium aspiration may be decreased by paying careful attention to fetal distress and initiating prompt delivery in the presence of fetal acidosis, late decelerations, or poor beat-to-beat variability. Amnio-infusion in cases of meconium-stained fluid lowers the rate of cesarean section and improves neonatal outcome. Immediate DeLee suctioning of the oropharynx after the head is delivered reduces the incidence of meconium aspiration.

Treatment.

Routine intubation to aspirate the lungs of vigorous infants born through meconium-stained fluid is not recommended. Depressed infants (those with hypotonia, bradycardia, fetal acidosis, or apnea) should undergo endotracheal intubation, and suction should be applied directly to the endotracheal tube to remove meconium from the airway. The risk associated with laryngoscopy and endotracheal intubation (bradycardia, laryngospasm, hypoxia, posterior pharyngeal laceration with pseudodiverticulum formation) is less than the risk of meconium aspiration syndrome in these severe circumstances.

Treatment of meconium aspiration pneumonia includes supportive care and standard management for respiratory distress. The oxygenation benefit of PEEP must be weighed against the risk of pneumothorax. Severe meconium aspiration may be complicated by persistent pulmonary hypertension and requires similar treatment. Patients who are refractory to conventional mechanical ventilation or HFV may benefit from surfactant therapy (regardless of gestational age), iNO, or extracorporeal membrane oxygenation (ECMO) (see Chapter 90.7).

Prognosis.

The mortality rate of meconium-stained infants is considerably higher than that of non-stained infants; meconium aspiration used to account for a significant proportion of neonatal deaths. Residual lung problems are rare but include symptomatic cough, wheezing, and persistent hyperinflation for up to 5–10 yr. The ultimate prognosis depends on the extent of CNS injury from asphyxia and the presence of associated problems such as pulmonary hypertension.

90.7 Persistent Pulmonary Hypertension of the Newborn (Persistent Fetal Circulation)

PPHN occurs in term and post-term infants. Predisposing factors include birth asphyxia, meconium aspiration pneumonia, early-onset sepsis, HMD, hypoglycemia,

polycythemia, maternal use of nonsteroidal anti-inflammatory drugs with in utero constriction of the ductus arteriosus, and pulmonary hypoplasia as a result of diaphragmatic hernia, amniotic fluid leak, oligohydramnios, or pleural effusions. PPHN is often idiopathic. Some patients with PPHN have low plasma arginine and nitric oxide metabolite concentrations and polymorphisms of the carbamoyl phosphate synthase gene, findings suggestive of a possible subtle defect in nitric oxide production. The incidence is 1/500–1,500 live births with a wide variation between different clinical centers.

Pathophysiology.

Persistence of the fetal circulatory pattern of right-to-left shunting through the PDA and foramen ovale after birth is due to excessively high pulmonary vascular resistance. Fetal pulmonary vascular resistance is usually elevated relative to fetal systemic or postnatal pulmonary pressure. This fetal state permits shunting of oxygenated umbilical venous blood to the left atrium (and brain) through the foramen ovale and bypasses the lungs through the ductus arteriosus to the descending aorta. After birth, pulmonary vascular resistance normally declines rapidly as a consequence of vasodilation secondary to gas filling the lungs, a rise in postnatal Pa_{O_2} , a reduction in P_{CO_2} , increased pH, and release of vasoactive substances. Increased neonatal pulmonary vascular resistance may (1) be maladaptive from an acute injury (e.g., not demonstrating normal vasodilation

in response to increased oxygen and other changes after birth); (2) be the result of increased pulmonary artery medial muscle thickness and extension of smooth muscle layers into the usually nonmuscular, more peripheral pulmonary arterioles in response to chronic fetal hypoxia; (3) be due to pulmonary hypoplasia (diaphragmatic hernia, Potter syndrome); (4) be obstructive as a result of polycythemia or total anomalous pulmonary venous return; or (5) be due to alveolar capillary dysplasia, a lethal, possibly familial disorder characterized by a thickened alveolar septum and a reduced number of small pulmonary arteries and capillaries. Apart from the etiology, profound hypoxia from right-to-left shunting and normal or elevated P_{CO_2} are present.

Clinical Manifestations.

Infants become ill in the delivery room or within the first 12?hr of life. PPHN related to polycythemia, idiopathic causes, hypoglycemia, or asphyxia may result in severe cyanosis with tachypnea, although initially, signs of respiratory distress may be minimal. Infants who have PPHN associated with meconium aspiration, group B streptococcal pneumonia, diaphragmatic hernia, or pulmonary hypoplasia usually exhibit cyanosis, grunting, flaring, retractions, tachycardia, and shock. Multiorgan involvement may be present (see Table 88–1). Myocardial ischemia, papillary muscle dysfunction with mitral and tricuspid regurgitation, and cardiac stunning produce cardiogenic shock with decreased pulmonary blood flow, tissue perfusion, and oxygen delivery. *The hypoxia is quite labile and often out of proportion to the findings on chest roentgenograms*.

Diagnosis.

PPHN should be suspected in all term infants who have cyanosis with or without fetal distress, intrauterine growth restriction, meconium-stained amniotic fluid, hypoglycemia, polycythemia, diaphragmatic hernia, pleural effusions, and birth asphyxia. Hypoxia is universal and is unresponsive to 100% oxygen given by oxygen hood, but it may respond transiently to hyperoxic hyperventilation administered after endotracheal intubation or to the application of a bag and mask. A Pa_{O_2} gradient between a preductal (right radial artery) and a postductal (umbilical artery) site of blood sampling greater than 20?mm Hg suggests right-to-left shunting through the ductus arteriosus. Real-time echocardiography combined with Doppler flow studies demonstrates right-to-left shunting across a patent foramen ovale and a ductus arteriosus. Deviation of the intra-atrial septum into the left atrium is seen in severe PPHN. Tricuspid or mitral insufficiency may be noted on auscultation as a holosystolic murmur and can be visualized echocardiographically together with poor contractility when PPHN is associated with myocardial ischemia. The degree of tricuspid regurgitation can be used to estimate pulmonary artery pressure. The 2nd heart sound is accentuated and not split. In asphyxia-associated and idiopathic PPHN, the chest roentgenogram is normal, whereas in PPHN associated with pneumonia and diaphragmatic hernia, it shows the specific lesions of parenchymal opacification and bowel in the chest, respectively. The *differential diagnosis* of PPHN includes cyanotic heart disease (especially obstructed total anomalous pulmonary venous return) and the associated etiologic entities that predispose to PPHN (e.g., hypoglycemia, polycythemia, sepsis).

Treatment.

Therapy is directed toward correcting any predisposing disease (hypoglycemia, polycythemia) and improving poor tissue oxygenation. The response to therapy is often unpredictable, transient, and complicated by the adverse effects of drugs or mechanical ventilation. Initial management includes oxygen administration and correction of acidosis, hypotension, and hypercapnia. Persistent hypoxia should be managed with intubation and mechanical ventilation.

The optimal approach to treatment is unclear and variable. One approach to the treatment of severe PPHN consists of instituting mechanical ventilation with or without pancuronium paralysis; ventilator settings are initially selected to achieve a Pa_{O_2} of 50–70?mm Hg and a P_{CO_2} of 50–55?mm Hg. Tolazoline (1?mg/kg), a nonselective a-adrenergic antagonist, is sometimes used as an adjunct to nonselectively vasodilate the pulmonary arterial system, but it also results in systemic hypotension, which is treated with volume expansion and dopamine. In another approach to treating severe PPHN, hyperventilation is used to reduce pulmonary vasoconstriction by lowering the P_{CO_2} (?25?mm Hg) and increasing the pH (7.50–7.55). Such management requires high peak inspiratory pressures and rapid respiratory rates, often necessitating the use of pancuronium paralysis for control of ventilation to achieve a Pa_{O_2} between 90 and 100?mm Hg. Complications of hyperventilation include hyperinflation with reduced elimination of carbon dioxide, reduced cardiac output, barotrauma, pneumothorax, decreased cerebral blood flow, increased fluid requirements, and edema resulting from paralysis. Alkalinization with

sodium bicarbonate also has been used to elevate plasma pH to induce pulmonary arterial vasodilation. Both methods of mechanical ventilation may be successful, and specific indications for one or the other have not been defined. Patients not responding to conventional ventilation may later respond to hyperventilation or HFV. Cardiogenic shock should be treated with inotropic agents such as dopamine and dobutamine.

Exogenous surfactant therapy has been beneficial in some patients. iNO, a potent and selective pulmonary vasodilator (equivalent to endothelium-derived relaxation factor), when given at an initial dose of 1–20?ppm, has improved oxygenation in patients with PPHN and reduced the need for ECMO. Although brief exposure to higher doses (40–80?ppm) appears to be safe, long-term treatment with 80?ppm increases the adverse effects. Responses to iNO include no improvement; initial improvement but not sustained, with ECMO being required; initial and sustained improvement, usually weaned by the 5th day of therapy; and an initial response but prolonged dependency, possibly as a result of pulmonary hypoplasia or alveolar capillary dysplasia. Methemoglobinemia is a rare but possible complication of iNO. The maximal safe duration of iNO therapy is unknown.

EXTRACORPOREAL MEMBRANE OXYGENATION.

In 5–10% of patients with PPHN (approximately 1/4,000 births), the response to 100% oxygen, mechanical ventilation, and drugs is poor. In such patients, the alveolar-arterial oxygen gradient (roughly at sea level, [760 - 47] - Pa_{CO_2} - Pa_{O_2}) or the oxygenation index (OI) has been used to predict mortality rates greater than 80%.

Alveolar-arterial gradients greater than 620 for 8–12?hr and an OI over 40 that is unresponsive to nitric oxide inhalation predict a high mortality rate and are indications for ECMO. ECMO has also been used to treat carefully selected, severely ill infants with hypoxemic respiratory failure caused by HMD, meconium aspiration pneumonia, congenital diaphragmatic hernia, PPHN, or sepsis.

ECMO is a form of cardiopulmonary bypass that augments systemic perfusion and provides gas exchange. Most experience has been with venoarterial bypass, which requires the placement of large catheters in the right internal jugular vein and carotid artery and, possibly, carotid artery ligation. If the artery is ligated, it should be repaired after stopping ECMO. Venovenous bypass avoids this ligation and provides gas exchange, but it does not support cardiac output. Blood is initially pumped through the ECMO circuit at a rate that approximates 80% of the estimated cardiac output of 150–200?mL/kg/min. Venous return passes through a membrane oxygenator, is warmed, and returns to the aortic arch. Venous oxygen saturation values are used to monitor

tissue oxygen delivery and subsequent extraction. The rate of ECMO flow is adjusted to achieve satisfactory venous oxygen saturation (>65%) and cardiovascular stability. When ECMO is started in an infant, the existing ventilator support is weaned to room air at a low rate and pressure to reduce the risk of oxygen toxicity and barotrauma, thus permitting time for the lungs to rest and heal.

Because ECMO requires complete heparinization to prevent clotting in the circuit, patients with or at risk for IVH (weight <2?kg, age <35 wk gestation) are not candidates for this therapy. In addition, infants for whom ECMO is being considered should have reversible lung disease, no signs of systemic bleeding, and an absence of severe asphyxia or lethal malformations, and they should have been ventilated for less than 7–10 days. Complications of ECMO include thromboembolism, air embolization, bleeding, stroke, seizures, atelectasis, cholestatic jaundice, thrombocytopenia, neutropenia, hemolysis, infectious complications of blood transfusions, edema formation, and systemic hypertension.

Prognosis.

Survival in patients with PPHN varies with the underlying diagnosis. The long-term outcome for infants with PPHN is related to the associated hypoxic-ischemic encephalopathy and the ability to reduce pulmonary vascular resistance. The long-term prognosis for infants who have PPHN and who survive after treatment with hyperventilation is comparable to that for infants who have underlying illnesses of equivalent severity (e.g., birth asphyxia, hypoglycemia, polycythemia). The outcome for infants who have PPHN treated with ECMO is also favorable; 85–90% survive, and 60–75% of survivors appear normal at 1–3.5 yr of age. Infants who have a diaphragmatic hernia associated with severe PPHN fare poorly if the pre-surgery and post-surgery P_{CO_2} exceeds 40?mm Hg despite mechanical ventilation. Such patients may respond to ECMO; rarely, it is not possible to wean them from bypass, or they expire after ECMO has been discontinued. Lung transplantation may benefit these infants.

90.8 Extrapulmonary Extravasation of Air (Pneumothorax, Pneumomediastinum, Pulmonary Interstitial Emphysema)

Asymptomatic pneumothorax, usually unilateral, is estimated to occur in 1–2% of all newborn infants; symptomatic pneumothorax and pneumomediastinum are less common. Pneumothorax occurs more frequently in males than in females and in term and post-term infants than in premature ones. The incidence is increased in infants with lung disease such as meconium aspiration and HMD; in those who have had vigorous resuscitation or are receiving assisted ventilation, especially if high inspiratory pressure or a continuous elevation of end-expiratory pressure is used; and in infants with urinary tract anomalies.

Etiology and Pathophysiology.

The most common cause of pneumothorax is overinflation resulting in alveolar rupture. It may be “spontaneous” and idiopathic or be due to underlying pulmonary disease such as lobar emphysema or rupture of a congenital or pneumonic cyst, to trauma, or to a “ball-valve” type of bronchial or bronchiolar obstruction resulting from aspiration. Air leaks occur during the 1st 24–36?hr in infants with meconium aspiration pneumonia and in infants with HMD when lung compliance is reduced, and later during the recovery phase of HMD if inspiratory pressure and PEEP are not reduced simultaneously with improved respiratory function.

Pneumothorax associated with pulmonary hypoplasia is common, occurs on the 1st day of life, and is due to reduced alveolar surface area and poorly compliant lungs. It is associated with disorders of decreased amniotic fluid volume (Potter syndrome; renal agenesis, renal dysplasia, chronic amniotic fluid leak), decreased fetal breathing movement (oligohydramnios, neuromuscular disease), pulmonary space-occupying lesions (diaphragmatic hernia, pleural effusion, chylothorax), and thoracic abnormalities (asphyxiating thoracic dystrophies).

Air from a ruptured alveolus escapes into the interstitial spaces of the lung, where it may cause *interstitial emphysema* or dissect along the peribronchial and perivascular connective tissue sheaths to the root of the lung. If the volume of escaped air is great enough, it may follow the vascular sheaths and cause mediastinal emphysema or a rupture with subsequent pneumomediastinum, pneumothorax, and subcutaneous emphysema. Rarely, increased mediastinal pressure may compress the pulmonary veins at the hilum and thereby interfere with venous return to the heart and cardiac output. On occasion, air may embolize into the circulation and produce cutaneous blanching, air in intravascular catheters, an air-filled heart on chest roentgenograms, and death.

Tension pneumothorax occurs if an accumulation of air within the pleural space is sufficient to elevate intrapleural pressure above atmospheric pressure. Unilateral tension pneumothorax results in impaired ventilation not only in the collapsed lung but also in the normal lung by a mediastinal shift to the other side. Compression of the vena cava and torsion of the great vessels may interfere with venous return.

Clinical Manifestations.

The physical findings of clinically *asymptomatic pneumothorax* are hyperresonance and diminished breath sounds over the involved side of the chest with or without tachypnea.

Symptomatic pneumothorax is characterized by respiratory distress, which varies from only an increased respiratory rate to severe dyspnea, tachypnea, and cyanosis. Irritability and restlessness or apnea may be the earliest signs. The onset is usually sudden but may be gradual; an infant may rapidly become critically ill. The chest may appear asymmetric with an increased anteroposterior diameter and bulging of the intercostal spaces on the affected side, and hyperresonance and diminished or absent

breath sounds may be present. The heart is displaced toward the unaffected side, and the diaphragm is displaced downward, as is the liver with right-sided pneumothorax. Because pneumothoraces may be bilateral in approximately 10% of patients, symmetry of findings does not rule out pneumothorax. In tension pneumothorax, signs of shock may be noted, and the apex of the heart is pushed away from the affected side.

Pneumomediastinum occurs in at least 25% of patients with pneumothorax and is usually asymptomatic. The degree of respiratory distress depends on the amount of trapped air. If it is great, bulging of the mid-thoracic area is observed, the neck veins are distended, and blood pressure is low. The last two findings are a result of blockage of the circulation by compression of the systemic and pulmonary veins. Although few clinical signs may exist, subcutaneous emphysema in newborn infants

is almost pathognomonic of pneumomediastinum.

Pulmonary interstitial emphysema (PIE) may precede the development of a pneumothorax or may occur independently and result in increasing respiratory distress as a result of decreased compliance, hypercapnia, and hypoxia. The latter is due to an increased alveolar-arterial oxygen gradient and intrapulmonary shunting. Progressive enlargement of blebs or air may result in cystic dilatation and respiratory deterioration resembling pneumothorax. In severe cases, PIE precedes the development of BPD. Avoidance of high inspiratory or mean ventilatory pressure may prevent the development of PIE. Treatment may include bronchoscopy in patients with evidence of mucus plugging, selective intubation and ventilation of the uninvolved bronchus, oxygen, general respiratory care, and HFV.

Diagnosis.

Pneumothorax and pneumomediastinum should be suspected in any newborn infant who shows signs of respiratory distress or who is restless or irritable or has a sudden change in condition. The diagnosis of pneumothorax is established roentgenographically, with the edge of the collapsed lung standing out in relief against the pneumothorax (see Fig. 405–1), and pneumomediastinum is diagnosed by hyperlucency around the heart border and between the sternum and the heart border (Fig. 90–8). Transillumination of the thorax is often helpful in the emergency diagnosis of pneumothorax; the affected side transmits excessive light. Associated renal anomalies are identified by ultrasonography. Pulmonary hypoplasia is suggested by

Figure 90.8-8 Pneumomediastinum in a newborn infant. The anteroposterior view demonstrates compression of the lungs, and the lateral view shows bulging of the sternum, each resulting from distention of the mediastinum by trapped air.

signs of uterine compression (extremity contractures), a small thorax on chest roentgenograms, severe hypoxia with hypercapnia, and signs of the primary disease (hypotonia, diaphragmatic hernia, Potter syndrome).

Pneumopericardium may be asymptomatic and require only general supportive treatment, but it is usually manifested as sudden shock with tachycardia, muffled heart sounds, and poor pulses suggesting tamponade, which requires prompt evacuation of entrapped air. **Pneumoperitoneum** from air dissecting through the diaphragmatic apertures during mechanical ventilation may also be confused with intestinal perforation.

Treatment.

Without a continued air leak, asymptomatic and mildly symptomatic small pneumothoraces require only close observation. Frequent small feedings may prevent gastric dilatation and minimize crying, which can further compromise ventilation and worsen the pneumothorax. Breathing 100% oxygen accelerates the resorption of free pleural air into blood by reducing the nitrogen tension in blood and producing a resultant nitrogen pressure gradient from the trapped air in the blood, but the benefit must be weighed against the risks of oxygen toxicity. With severe respiratory or circulatory embarrassment, emergency needle aspiration is indicated. Either immediately or after needle aspiration, a chest tube should be inserted and attached to underwater seal drainage. Severe localized interstitial emphysema may respond to selective bronchial intubation. Judicious use of pancuronium (Pavulon) in infants fighting the ventilator may reduce the incidence of pneumothorax. Surfactant therapy for RDS reduces the incidence of pneumothorax.

90.9 Pulmonary Hemorrhage

Pulmonary hemorrhage is a rare, but catastrophic complication with a high risk of morbidity and mortality. Massive pulmonary hemorrhage is present in 15% of neonates who come to autopsy in the 1st 2 wk of life. The reported incidence at autopsy varies

from 1 to 4/1,000 live births. About three fourths of patients weigh less than 2,500?g at birth.

Most infants in whom pulmonary hemorrhage is demonstrated at autopsy have had symptoms of respiratory distress that are indistinguishable from those of HMD. The onset may occur at birth or may be delayed several days. Hemorrhagic pulmonary edema is the source of blood in many cases and is associated with significant ductal shunting and high pulmonary blood flow. In severe cases, cardiovascular collapse, poor lung compliance, profound cyanosis, and hypercapnia may be present. Roentgenographic findings are varied and nonspecific and range from minor streaking or patchy infiltrates to massive consolidation.

The incidence of pulmonary hemorrhage is increased in association with acute pulmonary infection, severe asphyxia, HMD, surfactant therapy, assisted ventilation, PDA, congenital heart disease, erythroblastosis fetalis, hemorrhagic disease of the newborn, thrombocytopenia, inborn errors of ammonia metabolism, and cold injury. Although in the majority of instances bleeding into other organs is observed at autopsy, bleeding other than through the nostrils and mouth and intraventricular bleeding are relatively rare during life and should suggest the possibility of an additional bleeding diathesis such as disseminated intravascular coagulation. Bleeding is predominantly alveolar in about two thirds of cases and interstitial in the rest. In some infants, the pulmonary hemorrhage represents hemorrhagic pulmonary

edema secondary to severe left-sided heart failure resulting from hypoxia.

The little available information that describes the prognosis of infants who bleed through the mouth or nostrils suggests that it is extremely poor. Death occurs in the 1st 48?hr of life in two thirds of infants who come to autopsy. Treatment includes blood replacement, PEEP, suctioning to clear the airway, intratracheal administration of epinephrine, and in some cases, HFV.

Acute pulmonary hemorrhage may also rarely occur in postneonatal full-term infants. The cause is unknown. These infants have acute respiratory distress with bilateral alveolar infiltrates and usually respond to intensive supportive treatment (see Chapter 388).

Chapter 91 - Digestive System Disorders

Barbara J. Stoll
Robert M. Kliegman

Vomiting.

Vomiting or, more often, regurgitation is a relatively frequent symptom during the neonatal period. In the first few hours after birth, infants may vomit mucus, occasionally blood streaked. This vomiting rarely persists after the first few feedings; it may be due to irritation of the gastric mucosa by material swallowed during delivery. If the vomiting is protracted, gastric lavage with physiologic saline solution may relieve it.

When vomiting occurs shortly after birth and is persistent, the possibilities of intestinal obstruction, metabolic disorders, and increased intracranial pressure must be considered. A history of maternal hydramnios suggests upper gastrointestinal (esophageal, duodenal, ileal) atresia. *Bile-stained emesis* suggests intestinal obstruction beyond the duodenum, but it may also be idiopathic. Abdominal roentgenograms (kidney-ureter-bladder and cross-table lateral views) should be performed in neonates with persistent emesis and in all infants with bile-stained emesis to detect air-fluid levels, distended bowel loops, characteristic patterns of obstruction (double bubble: duodenal atresia), and pneumoperitoneum (intestinal perforation). A barium swallow roentgenogram with small bowel follow-through is indicated in the presence of bilious emesis.

Obstructive lesions of the digestive tract are the most frequent gastrointestinal anomalies (see Chapters 300 , 310 , 311 and 313). Vomiting from esophageal obstruction occurs with the 1st feeding. The diagnosis of esophageal atresia can be suspected if unusual drooling from the mouth is observed and if resistance is encountered during an attempt to pass a catheter into the stomach. The diagnosis should be made before the infant chokes on oral feedings and is at risk for aspiration pneumonia. Infantile achalasia (cardiospasm), a rare cause of vomiting in newborn infants, is demonstrable roentgenographically by obstruction at the cardiac end of the esophagus without organic stenosis. Regurgitation of feedings because of continuous relaxation of the esophageal-gastric sphincter, or chalasia, is a cause of vomiting. Keeping the infant in a semi-upright position, thickening the feeding, or administering prokinetic drugs can control it.

Vomiting because of *obstruction of the small intestine* usually begins on the 1st day of life and is frequent, persistent, usually non-projectile, copious, and unless the obstruction is above the ampulla of Vater, bile stained; it is associated with abdominal distention, visible deep peristaltic waves, and reduced or absent bowel movements. Malrotation with obstruction from midgut volvulus is an acute emergency that must be considered. Upright roentgenographic films of the abdomen show the distribution of air in the intestine and often aid in locating the site of the obstruction; malrotation will be identified by contrast studies. Normally, air can be demonstrated roentgenographically in the jejunum by 15–60?min, in the ileum by 2–3?hr, and in the colon by 3?hr after birth. Absence of rectal gas at 24?hr is abnormal. Persistent vomiting may occur with congenital diaphragmatic hernia. The vomiting associated with pyloric stenosis may begin any time after birth but does not assume its characteristic pattern before the 2nd–3rd wk. Vomiting with obstipation is a common early sign of Hirschsprung disease. Vomiting may occur with many other disturbances that do not obstruct the digestive tract, such as milk allergy, adrenal hyperplasia of the salt-losing variety, galactosemia, hyperammonemia, organic acidemias, increased intracranial pressure, septicemia, meningitis, and urinary tract infection. In the majority of instances, it is simply regurgitation from overfeeding or from failure to permit the infant to eructate swallowed air. (See Chapter 304 for a discussion of gastric emptying and gastroesophageal reflux.)

Thrush (Oral Candidiasis).

Thrush of the mouth occurs in healthy infants. Transmission of fungi from maternal vaginal moniliasis to the infant's oral mucosa is the primary means of infection in healthy newborns. Secondary cases may develop in the hospital nursery as a result of direct or indirect contact with infected infants, caretakers, or contaminated supplies. In an otherwise healthy infant, oral thrush is usually a self-limited infection, but treatment is advised, especially in the presence of candidal diaper rash (Chapter 215.1).

Later in infancy, oral thrush is rare except in debilitated infants, in those receiving antibiotic or immunosuppressive therapy, and in those with AIDS. Infants with AIDS also manifest failure to thrive, psychomotor retardation, hepatosplenomegaly, diarrhea, lymphadenopathy, and hypergammaglobulinemia (see Chapter 254).

Diarrhea.

See Chapters 48.1 , 48.2 , 321 , and 322 .

Constipation.

More than 90% of full-term newborn infants pass meconium within the 1st 24?hr. The possibility of intestinal obstruction should be considered in any infant who does not pass meconium by 24–36?hr. Intestinal atresia, stricture, or stenosis, congenital aganglionic megacolon, milk bolus obstruction, meconium ileus, or meconium plugs may be manifested as constipation. About 20% of very low birthweight (VLBW) infants do not pass meconium within the 1st 24?hr. Constipation not present from birth but appearing during the 1st mo of life suggests short-segment congenital aganglionic megacolon, hypothyroidism, strictures after necrotizing enterocolitis (NEC), or anal stenosis. It must be kept in mind that infrequent bowel movements do not necessarily mean constipation. A breast-fed infant usually has frequent bowel movements, whereas a formula-fed infant may have one to two movements a day or every other day.

Meconium Plugs.

Lower colonic or anorectal plugs (Fig. 91–1 (Figure Not Available)) with a lower than normal water content may cause intestinal obstruction. Rarely, a firm mass of meconium may form elsewhere in the intestine and cause intrauterine intestinal obstruction and meconium peritonitis unrelated to cystic fibrosis (CF). Anorectal plugs may also cause intestinal ulceration and perforation. Meconium plugs are associated with small left colon syndrome in infants of diabetic mothers and with CF, rectal aganglionosis, maternal drug abuse, and magnesium sulfate therapy for preeclampsia. The plug may be evacuated by irrigating it with isotonic sodium chloride solution. Enemas with the iodinated contrast medium Gastrografin usually induce passage of the plug, presumably because the high osmolarity (1,900?mOsm/L) of the medium draws fluid rapidly into the intestinal lumen and loosens inspissated material. Such rapid loss of fluid into the bowel may result in acute dehydration and shock, so it is advisable to dilute the contrast material with an equal amount of water, correct any existing dehydration, and provide intravenous fluids during and for several hours after the procedure. *After removal of a meconium plug, the infant should be observed closely for the possible presence of congenital aganglionic megacolon.*

Figure 91-1 (Figure Not Available) This plug of meconium and mucus (scale in cm) caused bowel obstruction in a premature infant. A radiograph showed marked gaseous distention and multiple fluid levels at 30?hr of age. Dramatic improvement occurred when the plug was passed after an enema. (From The abnormal fetus. In Beischer NA, Mackay EV, Colditz PB [editors]: *Obstetrics and the Newborn*, 3rd ed. Philadelphia, WB Saunders, 1997.)

91.1 Meconium Ileus in Cystic Fibrosis

In a newborn infant, impaction of meconium causes intestinal obstructions often associated with CF. The absence of fetal pancreatic enzymes limits normal digestive activities in the intestine, and meconium becomes viscid and mucilaginous. It clings to the intestinal wall and moves with difficulty. The inspissated and impacted meconium fills the intestinal canal but is most concentrated in the lower part of the ileum. Clinically, the pattern is that of congenital intestinal obstruction with or without intestinal perforation. Abdominal distention is prominent, and persistent vomiting soon occurs. Infrequently, one or more inspissated meconium stools may be passed shortly after birth.

The *differential diagnosis* involves other causes of intestinal obstruction, including intestinal pseudo-obstruction and pancreatic insufficiency; an exact diagnosis cannot be made except at laparotomy. A presumptive diagnosis can be made on the basis of a history of CF in a sibling, by palpation of doughy or cordlike masses of intestines through the abdominal wall, and by the roentgenographic appearance.

Roentgenographically, in contrast to the generally evenly distended intestinal loops above an atresia, the loops may vary in width and are not as evenly filled with gas. At points of heaviest meconium concentration, the infiltrated gas may create a bubbly granular appearance (Figs. 91–2 and 91–3). It is technically difficult to do a sweat test in a neonate. Genetic testing confirms the diagnosis of CF.

Treatment is high Gastrografin enemas as described previously for meconium plugs. If they are unsuccessful or if perforation of the bowel wall is suspected, laparotomy is performed and the ileum opened at the point of greatest diameter of the impaction. Approximately 50% of infants have associated intestinal atresia, stenosis, or volvulus that does not respond to contrast enema and requires surgery. The inspissated meconium is removed by

Figure 91.1-2 Meconium ileus. Impacted meconium with small amounts of air interspersed throughout it can be seen in loops of intestine on the right side of the abdomen. The intestinal loops above this impaction are greatly distended.

Figure 91.1-3 Meconium ileus. The colon, outlined by contrast material, is small because meconium has not reached it.

gentle and patient irrigation with warm isotonic sodium chloride or acetylcysteine (Mucomyst) solution introduced through a fine catheter, which may be passed between the impaction and the bowel wall. Most infants with meconium ileus survive the neonatal period. If associated with CF, the long-term prognosis depends on the severity of the underlying disease (Chapter 402).

Meconium Peritonitis.

Perforation of the intestine may occur in utero or shortly after birth. Either natural processes may seal the tear relatively quickly with only a small amount of meconium escaping, or the meconium contents may largely be emptied into the peritoneal cavity. Such perforations occur most often as a complication of meconium ileus in infants with CF, but the perforation is occasionally due to a meconium plug or intestinal obstruction of another cause.

When an intestinal perforation has spontaneously sealed and only a small amount of meconium has escaped, the event may never be detected, except when meconium becomes calcified and is later fortuitously discovered on roentgenograms of the abdomen. Alternatively, the clinical picture may be dominated by the signs of intestinal obstruction (as in meconium ileus) or peritonitis. Characteristically noted are abdominal distention, vomiting, and absence of stools. Treatment consists primarily of elimination of the intestinal obstruction and drainage of the peritoneal cavity.

91.2 Neonatal Necrotizing Enterocolitis (NEC)

NEC is the most common life-threatening emergency of the gastrointestinal tract in the newborn period. The disease is characterized by various degrees of mucosal or transmural necrosis of the intestine. The cause of NEC remains unclear but is most likely multifactorial. Its incidence is 1–5% of infants in neonatal intensive care units. Both incidence and case fatality rates increase with decreasing birthweight and gestational age. Because very small, ill preterm infants are particularly susceptible to NEC, a rising incidence may reflect improved survival of this high-risk group of patients. The disease is rare in term infants.

Pathology and Pathogenesis.

Many factors may contribute to the development of a necrotic segment of intestine, gas accumulation in the submucosa of the bowel wall (pneumatosis intestinalis), and progression of the necrosis to perforation, sepsis, and death. The distal part of the ileum and the proximal segment of colon are involved most frequently; in fatal cases, gangrene may extend from the stomach to the rectum. The concept of “risk factors” for NEC is controversial. The triad of intestinal ischemia, oral feedings (metabolic substrate), and pathogenic organisms has been linked to NEC. The greatest risk factor for NEC is prematurity. Although no proven cause has been established for NEC, the disease probably results from an interaction between mucosal injury caused by a variety of factors (ischemia, infection, inflammation) and the host's response to that injury (circulatory, immunologic, inflammatory). Clustering of cases suggests a primary role for an infectious agent. Various bacterial and viral agents, including *Escherichia coli, Klebsiella*, *Clostridium perfringens, Staphylococcus epidermidis,* and rotavirus, have been recovered from cultures. Nonetheless, in most situations no pathogen is identified. NEC rarely occurs before the initiation of enteral feeding and is much less common in infants fed human milk. Aggressive enteral feeding may predispose to the development of NEC.

Clinical Manifestations.

Infants with NEC have a variety of signs and symptoms and may have either an insidious or sudden catastrophic onset (Box 91–1). The onset of NEC usually occurs in the first 2 wk but can be as late as 3 mo of age in VLBW infants. Age at onset is inversely related to gestational age. The first signs are abdominal distention with gastric retention. Obvious bloody stools are seen in 25% of patients. Because of nonspecific signs, sepsis may be suspected before an intestinal lesion is noted. The spectrum of illness is broad and ranges from mild disease with only guaiac-positive stools to severe illness with bowel perforation, peritonitis, systemic inflammatory response syndrome, shock, and death. Progression may be rapid, but it is unusual for the disease to progress from mild to severe after 72?hr.

Diagnosis.

A very high index of suspicion in treating infants at risk is essential. Plain abdominal roentgenograms may demonstrate pneumatosis intestinalis, a finding that is diagnostic of NEC in a newborn infant; 50–75% of patients have pneumatosis when treatment is started (Fig. 91–4). Portal vein gas is a sign of severe disease, and pneumoperitoneum indicates a perforation (Figs. 91–4 and 91–5). Hepatic ultrasonography may detect portal venous gas despite normal abdominal

roentgenograms.

The *differential diagnosis* of NEC includes specific infections (systemic or intestinal), obstruction, volvulus, and isolated intestinal perforation. Idiopathic focal intestinal perforation can occur after the early use of postnatal steroids and indomethacin. Pneumoperitoneum develops in such patients, but they are usually less ill than those with NEC.

Box 91.2-1. Signs and Symptoms Associated with Necrotizing Enterocolitis

GASTROINTESTINAL	SYSTEMIC
Abdominal distention	Lethargy
Abdominal tenderness	Apnea/respiratory distress
Feeding intolerance	Temperature instability
Delayed gastric emptying	"Not right"
Vomiting	Acidosis (metabolic and/or respiratory)
Occult/gross blood in stool	
Change in stool pattern/diarrhea	Glucose instability
Abdominal mass	Poor perfusion/shock
Erythema of abdominal wall	Disseminated intravascular coagulopathy
	Positive results of blood cultures

From Kanto WP Jr, Hunter JE, Stoll BJ: Recognition and medical management of necrotizing enterocolitis. Clin Perinatol 1994; 21:335–46.

Figure 91.2-4 Necrotizing enterocolitis. A kidney-ureter-bladder film demonstrates abdominal distention, hepatic portal venous gas *(arrow),* and a bubbly appearance of pneumatosis intestinalis *(arrowhead; right lower quadrant).* The latter two signs are thought to be pathognomonic for neonatal necrotizing enterocolitis.

Treatment.

Intensive therapy is advisable for suspected as well as diagnosed cases. Cessation of feeding, nasogastric decompression, and administration of intravenous fluids with careful attention to respiratory status, coagulation profile, and acid-base and electrolyte balance are very important. Once blood has been drawn for culture, systemic antibiotics (with broad coverage for gram-negative and other organisms) should be started. If present, umbilical catheters should be removed, but with good intravenous access maintained. Ventilation should be assisted if distention is contributing to hypoxia and hypercapnia. If hypotension develops, resuscitation with crystalloid, blood, plasma, and/or dopamine is essential.

The patient's course should be monitored by performing frequent cross-table lateral abdominal roentgenograms to detect perforation and by serial determination of the hematocrit and platelet, electrolyte, and acid-base status. Gown and glove isolation and grouping infants at similar increased risk into cohorts separate from other infants should be instituted to contain an epidemic.

A surgeon should be consulted early in the course of treatment. Evidence of perforation (free air) is an indication for laparotomy and resection of necrotic bowel. Brown paracentesis fluid with organisms on Gram stain suggests perforation. Failure to respond to medical management, a single fixed bowel loop, erythema of the abdominal wall, and a palpable mass are additional indications for exploratory laparotomy, resection of necrotic bowel, and external ostomy diversion. Ideally, surgery should be performed after intestinal necrosis develops, but before perforation and peritonitis occur. Noninvasive diagnosis of intestinal necrosis with abdominal MRI is being studied. The role of peritoneal drainage in lieu of laparotomy in a patient with perforation secondary to NEC is unclear. Peritoneal drainage may be helpful for patients in extremis with peritonitis who are too unstable to withstand surgery. Peritoneal drainage tends to be more successful in patients with isolated intestinal perforation. Such patients tend to have a lower birthweight, are more likely to not be receiving oral feeding, and are prone to perforation at an earlier postnatal age than are patients with perforation related to NEC. In many patients with isolated intestinal perforation treated by drainage, no further surgical procedure is needed; a small subgroup may require later surgery to repair an intestinal stricture or fistula.

Prognosis.

Medical management fails in about 20% of patients with pneumatosis intestinalis at diagnosis; of these, 9–25% die. Early postoperative complications include wound infection and dehiscence and stomal problems (prolapse, necrosis). Intestinal strictures develop at the site of the necrotizing lesion in about 10% of surgically or medically managed patients. Resection of the obstructing stricture is curative. Complications of NEC after massive intestinal resection include short-bowel syndrome (malabsorption, growth failure, malnutrition), complications of total

parenteral alimentation related to central venous catheters (sepsis, thrombosis), and cholestatic jaundice. No prevention strategy has proved to be effective, although the risk of NEC in preterm infants is significantly lower in infants who are fed only breast milk. Minimal enteric feedings (gut stimulation) prior to bolus feedings may reduce the incidence of NEC; early initiation of aggressive feeding protocols may increase its incidence in VLBW infants.

Figure 91.2-5 Intestinal perforation. A cross-table abdominal roentgenogram in a patient with neonatal necrotizing enterocolitis demonstrates marked distention and massive pneumoperitoneum as evidenced by the free air below the anterior abdominal wall.

91.3 Jaundice and Hyperbilirubinemia in the Newborn

Hyperbilirubinemia is a common and, in most cases, benign problem in neonates. Nonetheless, untreated, severe indirect hyperbilirubinemia is potentially neurotoxic, and conjugated-direct hyperbilirubinemia often signifies a serious hepatic or systemic illness. Jaundice is observed during the 1st wk of life in approximately 60% of term infants and 80% of preterm infants. The color usually results from the accumulation in skin of unconjugated, nonpolar, lipid-soluble bilirubin pigment (indirect reacting) formed from hemoglobin by the action of heme oxygenase, biliverdin reductase, and nonenzymatic reducing agents in the reticuloendothelial cells; it may also be due in part to deposition of the pigment after it has been converted in the liver cell microsome by the enzyme uridine diphosphoglucuronic acid (UDP)-glucuronyl transferase to the polar, water-soluble ester glucuronide of bilirubin (direct reacting). The unconjugated form is neurotoxic in infants at certain concentrations and under various conditions. Conjugated bilirubin is not neurotoxic but indicates a potentially serious disorder.

Etiology.

A newborn infant's metabolism of bilirubin is in transition from the fetal stage, during which the placenta is the principal route of elimination of the lipid-soluble bilirubin, to the adult stage, during which the water-soluble conjugated form is excreted from hepatic cells into the biliary system and then into the gastrointestinal tract. Unconjugated hyperbilirubinemia may be caused or increased by any factor that (1) increases the load of bilirubin to be metabolized by the liver (hemolytic anemias, polycythemia, shortened red cell life as a result of immaturity or transfused cells, increased enterohepatic circulation, infection), (2) damages or reduces the activity of the transferase enzyme (genetic deficiency, hypoxia, infection, possibly hypothermia and thyroid deficiency), (3) competes for or blocks the transferase enzyme (drugs and other substances requiring glucuronic acid conjugation for excretion), or (4) leads to an absence or decreased amounts of the enzyme or to reduction of bilirubin uptake by liver cells (genetic defect, prematurity). The toxic effects of elevated levels of unconjugated bilirubin in serum are increased by factors that reduce the retention of bilirubin in the circulation (hypoproteinemia, displacement of bilirubin from its binding sites on albumin by competitive binding of drugs such as sulfisoxazole and moxalactam, Chuen-Lin herbal tea, acidosis, increased free fatty acid concentration secondary to hypoglycemia, starvation, or hypothermia) or by factors that increase the permeability of the blood-brain barrier or nerve cell membranes to bilirubin or increase the susceptibility of brain cells to its toxicity, such as asphyxia, prematurity, hyperosmolality, and infection. Early feeding decreases whereas breast-feeding and dehydration increase serum levels of bilirubin. Meconium has 1?mg bilirubin/dL and may contribute to jaundice by the enterohepatic circulation after deconjugation by intestinal glucuronidase (Fig. 91–6). Drugs such as oxytocin and chemicals used in the nursery such as phenolic detergents may also produce unconjugated hyperbilirubinemia. The mnemonic JAUNDICE can be helpful in recalling risk factors for unconjugated hyperbilirubinemia (see Box 91–2).

Clinical Manifestations.

Jaundice may be present at birth or may appear at any time during the neonatal

period, depending on the cause. Jaundice usually begins on the face and, as serum levels increase, progresses to the abdomen and then the feet. Dermal pressure may reveal the anatomic progression of jaundice (face, ?5?mg/dL; mid-abdomen, ?15?mg/dL; soles, ?20?mg/dL), but clinical examination cannot be depended on to estimate blood levels. Jaundice to the mid-abdomen, signs or symptoms, high-risk factors that suggest nonphysiologic jaundice (Box 91–2), or hemolysis must be evaluated further. Noninvasive techniques for transcutaneous measurement of bilirubin that correlate well with serum levels may be used to screen infants, but determination of a serum bilirubin level is indicated for patients with progressing jaundice, symptoms, or a risk for hemolysis or sepsis. Jaundice resulting from deposition of indirect bilirubin in the skin tends to appear bright yellow or

Figure 91.3-6 The neonatal production rate of bilirubin is 6–8?mg/kg/24?hr (in contrast to 3–4?mg/kg/24?hr in adults). Water-insoluble bilirubin is bound to albumin. At the plasma-hepatocyte interface, a liver membrane carrier (bilitranslocase) transports bilirubin to a cytosolic binding protein (ligandin or Y protein, now known to be glutathione *S*-transferase), which prevents back-absorption to plasma. Bilirubin is converted to bilirubin monoglucuronide (BMG) or diglucuronide (BDG) by several classes of the enzyme bilirubin glucuronyl transferase. Neonates excrete more BMG than adults do. In the fetus, conjugated lipid-insoluble BMG and BDG must be deconjugated by tissue ß-glucuronidases to facilitate placental transfer of lipid-soluble unconjugated bilirubin across the placental lipid membranes. After birth, intestinal or milk-containing glucuronidases contribute to the enterohepatic recirculation of bilirubin and possibly to the development of hyperbilirubinemia.

---

orange, and jaundice of the obstructive type (direct bilirubin) has a greenish or muddy yellow cast. This difference is usually apparent only in severe jaundice. Affected infants may be lethargic and may feed poorly. Signs of kernicterus rarely appear on the 1st day of jaundice (Chapter 91.4).

Differential Diagnosis.

Jaundice, consisting of either indirect or direct bilirubin, that is present at birth or appears within the 1st 24?hr of life requires immediate attention and may be due to erythroblastosis fetalis, concealed hemorrhage, sepsis, or intrauterine infections, including syphilis, cytomegalic inclusion disease, rubella, and congenital toxoplasmosis. Hemolysis is suggested by a rapid rise in serum bilirubin (>0.5?mg/dL/hr), anemia, pallor, reticulocytosis, hepatosplenomegaly, and a positive family history. An unusually high proportion of direct-reacting bilirubin may characterize jaundice in infants who have received intrauterine transfusions. Jaundice that first appears on the 2nd or 3rd day is usually “physiologic” but may represent a more severe form. Familial nonhemolytic icterus (Crigler-Najjar syndrome) and early-onset breast-feeding jaundice are seen initially on the 2nd or 3rd day. *Jaundice appearing after the 3rd day and within the 1st wk should suggest bacterial sepsis or urinary tract infection;* it may be due to other infections, notably syphilis, toxoplasmosis, cytomegalovirus, or enterovirus. Jaundice secondary to extensive ecchymosis or hematoma may occur during the 1st day or later, especially in premature infants. Polycythemia may lead to early jaundice.

Jaundice that is noted initially after the 1st wk of life suggests breast milk jaundice, septicemia, congenital atresia or paucity of the bile ducts, hepatitis, galactosemia, hypothyroidism, CF, congenital hemolytic anemia (spherocytosis), or possibly the crises of other hemolytic anemias (such as pyruvate kinase and other glycolytic enzyme deficiencies or hereditary nonspherocytic anemia) or hemolytic anemia related to drugs (as in congenital deficiencies of the enzymes glucose-6-phosphate dehydrogenase [G6PD] or glutathione synthetase, reductase, or peroxidase) (Fig. 91–7).

Persistent jaundice during the 1st mo of life suggests inspissated bile syndrome (which may follow hemolytic disease of the newborn), hyperalimentation-associated cholestasis, hepatitis, cytomegalic inclusion disease, syphilis, toxoplasmosis, familial nonhemolytic icterus, congenital atresia of the bile ducts, or

galactosemia. Rarely, physiologic jaundice may be prolonged for several weeks, as in infants with hypothyroidism or pyloric stenosis.

Low-risk jaundiced infants who are full term and asymptomatic may be evaluated by monitoring serum total bilirubin levels. Regardless of the gestational age or time of appearance of jaundice, those with significant hyperbilirubinemia and all patients with symptoms or signs require a complete diagnostic evaluation, which should include determination of the direct and indirect bilirubin fractions, hemoglobin, reticulocyte count, and blood type, a Coombs test, and examination of a peripheral blood smear. Indirect-reacting bilirubinemia, reticulocytosis, and a smear demonstrating evidence of red blood cell destruction suggest hemolysis; in the absence of blood group incompatibility, non-immunologically induced hemolysis should be considered. If direct-reacting hyperbilirubinemia is present, hepatitis, congenital bile duct disorders (atresia, paucity, Byler disease), cholestasis, inborn errors of metabolism, CF, and sepsis are diagnostic possibilities. If the reticulocyte count, Coombs test, and direct bilirubin are normal, physiologic or pathologic indirect hyperbilirubinemia may be present (see Fig. 91–7).

Physiologic Jaundice (Icterus Neonatorum).

Under normal circumstances, the level of indirect-reacting bilirubin in umbilical cord serum is 1–3?mg/dL and rises at a rate of less than 5?mg/dL/24?hr; thus, jaundice becomes visible on the 2nd–3rd day, usually peaking between the 2nd and 4th days at 5–6?mg/dL and decreasing to below 2?mg/dL between the 5th and 7th days of life. Jaundice associated with these changes is designated “physiologic” and is believed to be the result of increased bilirubin production after the breakdown of fetal red blood cells combined with transient limitation in the conjugation of bilirubin by the liver.

Overall, 6–7% of full-term infants have indirect bilirubin levels greater than 12.9?mg/dL and less than 3% have levels greater than 15?mg/dL. Risk factors for indirect hyperbilirubinemia include maternal diabetes, race (Chinese, Japanese, Korean, and Native American), prematurity, drugs (vitamin K_3 , novobiocin), altitude, polycythemia, male sex, trisomy 21, cutaneous bruising, cephalohematoma, oxytocin induction, breast-feeding, weight loss (dehydration or caloric deprivation), delayed bowel movement, and a sibling who had physiologic jaundice (see Box 91–2). A family history of neonatal jaundice, exclusive breast-feeding, bruising, cephalohematoma, Asian race, and maternal age older than 25 yr identify approximately 60% of cases of extreme hyperbilirubinemia. In infants without these variables, indirect bilirubin levels rarely rise above 12?mg/dL, whereas infants with several risk factors are more likely to have higher bilirubin levels. Indirect bilirubin levels in full-term infants decline to adult levels (1?mg/dL) by 10–14 days of life.

Prediction of which neonatal infants are at risk for exaggerated physiologic jaundice can be based on hour-specific bilirubin levels in the 1st 24–72?hr of life (Fig. 91–8).

Persistent indirect hyperbilirubinemia beyond 2 wk suggests hemolysis, hereditary glucuronyl transferase deficiency, breast milk jaundice, hypothyroidism, or intestinal obstruction. Jaundice associated with pyloric stenosis may be due to caloric deprivation, deficiency of hepatic UDP-glucuronyl transferase, or ileus-induced increased enterohepatic circulation of bilirubin.

Figure 91.3-8 Risk designation of term and near-term well newborns based on their hour-specific serum bilirubin values. The high-risk zone is designated by the 95th percentile track. The intermediate-risk zone is subdivided into upper and lower risk zones by the 75th percentile track. The low-risk zone has been electively and statistically defined by the 40th percentile track. *(Dotted extensions* are based on less than 300 total serum bilirubin values/epoch.) (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics* 1999;103:9.)

In premature infants, the rise in serum bilirubin tends to be the same or a little slower than that in term infants, but it is of longer duration, which generally results in higher levels, the peak being reached between the 4th and 7th days; the pattern depends on the time required for the development of mature mechanisms for the metabolism and excretion of bilirubin. Peak levels of 8–12?mg/dL are not usually reached until the 5th–7th day, and jaundice is infrequently observed after the 10th day.

The diagnosis of physiologic jaundice in term or preterm infants can be established only by precluding known causes of jaundice on the basis of the history and clinical and laboratory findings (Table 91–1). In general, a search to determine the cause of jaundice should be made if (1) it appears in the 1st 24–36?hr of life, (2) serum bilirubin is rising at a rate faster than 5?mg/dL/24?hr, (3) serum bilirubin is greater than 12?mg/dL in full-term (especially in the absence of risk factors) or 10–14?mg/dL in preterm infants, (4) jaundice persists after 10–14 days of life, or (5) direct-reacting bilirubin is greater than 2?mg/dL at any time. Among other factors suggesting a nonphysiologic cause of jaundice are a family history of hemolytic disease, pallor, hepatomegaly, splenomegaly, failure of phototherapy to lower bilirubin, vomiting, lethargy, poor feeding, excessive weight loss, apnea, bradycardia, abnormal vital signs (including hypothermia), light-colored stools, dark urine positive for bilirubin, and signs of kernicterus (Chapter 91.4).

Pathologic Hyperbilirubinemia.

Jaundice and its underlying hyperbilirubinemia are considered pathologic if their time of appearance, duration, or pattern of serially determined serum bilirubin concentrations varies significantly from that of physiologic jaundice or if the course is compatible with physiologic jaundice but other reasons exist to suspect that the

infant is at special risk from the neurotoxicity of unconjugated bilirubin. It may not be possible to precisely determine the cause of an abnormal elevation of unconjugated bilirubin. Many of these infants have an associated risk factor such as Asian race, prematurity, breast-feeding, or weight loss; hence, the terms exaggerated

From Brown AK: Pediatr Clin North Am 1962;9:589.

physiologic jaundice and hyperbilirubinemia of the newborn are used for infants whose primary problem is probably a deficiency or inactivity of bilirubin glucuronyl transferase (e.g., Gilbert syndrome) rather than an excessive load of bilirubin for excretion (see Box 91–2). The combination of G6PD deficiency and a mutation of the promoter region of UDP-glucuronyl transferase 1 produces indirect hyperbilirubinemia in the absence of signs of hemolysis. Nonphysiologic hyperbilirubinemia may also be caused by mutations in the gene for bilirubin UDP-glucuronyl transferase.

The greatest risk associated with hyperbilirubinemia is the development of kernicterus (bilirubin encephalopathy) at high indirect serum bilirubin levels (Chapter 91.4). The level of serum bilirubin associated with kernicterus is dependent in part on the cause of the jaundice. Kernicterus develops at lower bilirubin levels in preterm infants and in the presence of asphyxia, intraventricular hemorrhage, hemolysis, or drugs that displace bilirubin from albumin. The exact serum bilirubin level that is harmful for VLBW infants is unclear. Kernicterus does occur in patients with breast milk jaundice but is very uncommon. The duration of exposure to bilirubin and the brain concentration of bilirubin are important factors for neurotoxicity.

Jaundice Associated with Breast-Feeding.

Significant elevations in unconjugated bilirubin (breast milk jaundice) develop in an estimated 2% of breast-fed term infants after the 7th day of life, with maximal concentrations as high as 10–30?mg/dL reached during the 2nd–3rd wk. If breast-feeding is continued, the hyperbilirubinemia gradually decreases and may then persist for 3–10 wk at lower levels. If nursing is discontinued, the serum bilirubin level falls rapidly, usually reaching normal levels within a few days. Cessation of breast-feeding for 1–2 days and substitution of formula for breast milk results in a rapid decline in serum bilirubin, after which nursing can be resumed without a return of the hyperbilirubinemia to its previously high levels. If indicated, phototherapy may be of benefit (Chapter 91.4). These infants have no other sign of illness; nonetheless, kernicterus

has been reported. The cause is unclear, but in some the milk contains a glucuronidase that may be responsible for jaundice.

This syndrome should be distinguished from an early-onset, accentuated unconjugated hyperbilirubinemia (breast-feeding jaundice) in the 1st wk of life, when breast-fed infants have higher bilirubin levels than formula-fed infants do (Fig. 91–9). Hyperbilirubinemia (>12?mg/dL) develops in 13% of breast-fed infants in the 1st wk of life and may be due to decreased milk intake with dehydration or reduced caloric intake. Giving supplements of glucose water to breast-fed infants is associated with higher bilirubin levels, in part because of reduced intake of the higher caloric density breast milk. Frequent breast-feeding (>10/24?hr), rooming-in with night feeding, and discouraging 5% dextrose or water supplementation may reduce the incidence of early breast-feeding jaundice.

Neonatal Hepatitis.

See Chapter 337.1 .

Congenital Atresia of the Bile Ducts.

See Chapter 337.1 . Jaundice persisting for more than 2 wk or associated with acholic stools and dark urine suggests biliary atresia. All such infants should have an immediate diagnostic evaluation, including determination of direct bilirubin.

Inspissated Bile Syndrome.

See Late Complications in Chapter 92 .

91.4 Kernicterus

Kernicterus, or bilirubin encephalopathy, is a neurologic syndrome resulting from the deposition of unconjugated bilirubin in the basal ganglia and brainstem nuclei. The pathogenesis of kernicterus is multifactorial and involves an interaction between unconjugated bilirubin levels, albumin binding and unbound bilirubin levels, passage across the blood-brain barrier, and neuronal susceptibility to injury. Disruption of the blood-brain barrier by disease, asphyxia, or other factors and maturational changes in blood-brain barrier permeability affect risk.

The precise blood level above which indirect-reacting bilirubin or free bilirubin will be toxic for an individual infant is unpredictable, but kernicterus is rare in healthy term infants and in the absence of hemolysis if the serum level is under 25?mg/dL. In previously healthy, predominantly breast-fed term

Figure 91.4-9 Distribution of maximal bilirubin levels during the 1st wk of life in breast-fed and formula-fed white infants over 2,500?g. (From Maisels J, Gifford K: Normal serum bilirubin levels in the newborn and the effect of breast-feeding. *Pediatrics* 1986;78:837.)

infants, kernicterus has developed when bilirubin levels exceed 30?mg/dL, although the range is wide (21–50?mg/dL). Its onset is usually in the 1st wk of life, but it may be delayed to the 2nd–3rd wk. The risk in infants with hemolytic disease (erythroblastosis fetalis) is directly related to serum bilirubin levels. The duration of exposure needed to produce toxic effects is also unknown. Little evidence suggests that a level of indirect bilirubin less than 25?mg/dL affects the IQ of healthy term infants without hemolytic disease. *Nonetheless, the less mature the infant, the greater the susceptibility to kernicterus.* Factors that potentiate the movement of bilirubin into brain cells and its adverse effects on them are discussed in Chapter 91.3 . In exceptional circumstances, kernicterus in VLBW infants with serum bilirubin concentrations as low as 8–12?mg/dL has been associated with an apparently cumulative effect of a number of these factors.

Clinical Manifestations.

Signs and symptoms of kernicterus usually appear 2–5 days after birth in term infants and as late as the 7th day in premature ones, but hyperbilirubinemia may lead to the syndrome at any time during the neonatal period. The early signs may be subtle and indistinguishable from those of sepsis, asphyxia, hypoglycemia, intracranial hemorrhage, and other acute systemic illnesses in a neonatal infant. Lethargy, poor feeding, and loss of the Moro reflex are common initial signs. Subsequently, the infant may appear gravely ill and prostrated, with diminished tendon reflexes and respiratory distress. Opisthotonos with a bulging fontanel, twitching of the face or limbs, and a shrill high-pitched cry may follow. In advanced cases, convulsions and spasm occur, with affected infants stiffly extending their arms in inward rotation with the fists clenched (Box 91–3). Rigidity is rare at this late stage.

Many infants who progress to these severe neurologic signs die; the survivors are usually seriously damaged but may appear to recover and for 2–3 mo show few abnormalities. Later in the 1st yr of life, opisthotonos, muscle rigidity, irregular movements, and convulsions tend to recur. In the 2nd yr, the opisthotonos and seizures abate, but irregular, involuntary movements, muscle rigidity, or in some infants, hypotonia increase steadily. By 3 yr of age, the complete neurologic syndrome is often apparent and consists of bilateral choreoathetosis with involuntary muscle spasms, extrapyramidal signs, seizures, mental deficiency, dysarthric speech, high-frequency hearing loss, squinting, and defective upward movement of the eyes. Pyramidal signs, hypotonia, and ataxia occur in a few infants. In mildly affected infants, the syndrome may be characterized only by mild to moderate neuromuscular incoordination, partial deafness, or “minimal brain dysfunction,” occurring singly or in combination; these problems may be inapparent until the child enters school (see Box 91–3).

Pathology.

The surface of the brain is usually pale yellow. On cutting, certain regions are characteristically stained yellow by

Box 91.4-3. Clinical Features of Kernicterus

ACUTE FORM

Phase 1 (1st 1–2 days): poor sucking, stupor, hypotonia, seizures

Phase 2 (middle of 1st wk): hypertonia of extensor muscles, opisthotonos, retrocollis, fever

Phase 3 (after the 1st wk): hypertonia

CHRONIC FORM

First year: hypotonia, active deep tendon reflexes, obligatory tonic neck reflexes, delayed motor skills

After 1st yr: movement disorders (choreoathetosis, ballismus, tremor), upward gaze, sensorineural hearing loss

From Dennery PA, Seidman DS, Stevenson DK: Neonatal hyperbilirubinemia. N Engl J Med 2001; 344: 581–90.

unconjugated bilirubin, particularly the corpus subthalamicum, hippocampus and adjacent olfactory areas, striate bodies, thalamus, globus pallidus, putamen, inferior clivus, cerebellar nuclei, and cranial nerve nuclei. Nonpigmented areas may also be damaged. Loss of neurons, reactive gliosis, and atrophy of involved fiber systems are found in late disease. The pattern of injury has been related to the development of oxidative enzyme systems in various regions of the brain and overlaps with that found in hypoxic brain damage. Evidence favors the hypothesis that bilirubin interferes with oxygen utilization by cerebral tissue, possibly by injuring the cell membrane; antecedent hypoxic injury increases the susceptibility of brain cells to injury. Gross bilirubin staining without the specific microscopic changes of kernicterus may not be the same entity.

Incidence and Prognosis.

By pathologic criteria, kernicterus will develop in one third of infants (all gestational ages) with untreated *hemolytic disease* and bilirubin levels in excess of 25–30?mg/dL. The incidence at autopsy in hyperbilirubinemic premature infants is 2–16% and is related to the risk factors discussed in Chapter 91.3 . Reliable estimates of the frequency of the clinical syndrome are not available because of the wide spectrum of manifestations. Overt neurologic signs have a grave prognosis; 75% or more of such infants die, and 80% of affected survivors have bilateral choreoathetosis with involuntary muscle spasms. Mental retardation, deafness, and spastic quadriplegia are common. Infants at risk should have screening hearing tests.

Kernicterus is not a disease of the past; there have been reports of cases associated with high levels of bilirubin and no obvious underlying cause. Some experts recommend universal screening for hyperbilirubinemia in the 1st 24–48?hr of life to detect infants at high risk for severe jaundice and neurotoxicity. The American Academy of Pediatrics (AAP) has identified potentially preventable causes of kernicterus: (1) early discharge (<48?hr) with no early follow-up (within 48?hr of discharge); this problem is particularly important in near-term infants (35–37 wk gestation); (2) failure to check the bilirubin level in an infant noted to be jaundiced in the 1st 24?hr; (3) failure to recognize the presence of risk factors for hyperbilirubinemia; (4) underestimating the severity of jaundice by clinical (i.e., visual) assessment; (5) lack of concern regarding the presence of jaundice; (6) delay in measuring the serum bilirubin level despite marked jaundice or delay in initiating phototherapy in the presence of elevated bilirubin levels; and (7) failure to respond to parental concern regarding jaundice, poor feeding, or lethargy. The AAP recommends the following: (1) any infant who is jaundiced before 24?hr requires measurement of the serum bilirubin level, and if it is elevated, the infant should be evaluated for possible hemolytic disease, and (2) follow-up should be provided within 2–3 days of discharge to all neonates discharged earlier than 48?hr after birth. Early follow-up is particularly important for infants younger than 38 wk gestation. The timing of follow-up depends on the age at discharge and the presence of risk factors. In some cases, follow-up within 24?hr is necessary. Using hour-specific bilirubin levels also helps predict risk (see Fig. 91–8).

Treatment of Hyperbilirubinemia.

Regardless of the cause, the goal of therapy is to prevent the concentration of indirect-reacting bilirubin in the blood from reaching levels at which neurotoxicity may occur; it is recommended that phototherapy and, if unsuccessful, exchange transfusion be used to keep the maximal total serum bilirubin below the levels indicated in Tables 91–2 (for preterm) and 91–3 (for healthy term infants without hemolysis). The risk of injury to the central nervous system from bilirubin must be balanced against the risk inherent in the treatment for each infant. Criteria for initiating phototherapy are not generally agreed on. Because phototherapy may require 6–12?hr to have a measurable effect, it must be started at bilirubin levels below those indicated for exchange transfusion.

TABLE 91.4-2 -- Suggested Maximal Indirect Serum Bilirubin Concentrations (mg/dL) in Preterm Infants

Birthweight (g)	Uncomplicated	Complicated[*]
<1,000	12–13	10–12
1,000–1,250	12–14	10–12
1,251–1,499	14–16	12–14
1,500–1,999	16–20	15–17
2,000–2,500	20–22	18–20

Phototherapy is usually started at 50–70% of the maximal indirect level. If values greatly exceed this level, if phototherapy is unsuccessful in reducing the maximal bilirubin level, or if signs of kernicterus are evident, exchange transfusion is indicated.

* *Complications include perinatal asphyxia, acidosis, hypoxia, hypothermia, hypoalbuminemia, meningitis, intraventricular hemorrhage, hemolysis, hypoglycemia, or signs of kernicterus.*

TABLE 91.4-3 -- Approach to Indirect Hyperbilirubinemia in Healthy Term Infants Without Hemolysis[*]

Age (hr)	Treatment Strategies		
	Phototherapy	***Intensive Phototherapy and Preparation for Exchange Transfusion[†]***	***Exchange Transfusion if Phototherapy Fails[‡]***
<24	§	§	§
24–48	=15–18	=25	=20
49–72	=18–20	=30	=25
>72	=20	=30	=25
>2 wk	¶	¶	¶

* *With hemolysis, exchange transfusion is initiated with an indirect bilirubin level of 20 or higher at any age.*
The precise level of unconjugated bilirubin in healthy breast-fed term infants that requires therapy is unknown. Treatment options include continued breast-feeding and initiation of phototherapy or interrupted breast-feeding (use formula as a substitute), with or without phototherapy.
If any signs of kernicterus are noted during evaluation or treatment as suggested anywhere in the table or at any level of bilirubin, emergency exchange transfusion must be performed.
† *If the initial bilirubin value is high, intense phototherapy should be initiated and preparation made for exchange transfusion. If phototherapy fails to reduce the bilirubin level to the levels noted on the column to the right, initiate exchange transfusion.*
‡ *Intensive phototherapy should be initiated for bilirubin levels in this column and usually reduces serum bilirubin levels 1–2?mg/dL in 4–6 hr. Such treatment is often associated with administration of intravenous fluids at 1–1.5 times maintenance; oral alimentation should also continue.*
§ *Jaundice in the 1st 24 hr of life is not seen in "healthy" infants (see Chapter 91.3). Hyperbilirubinemia of this degree within 48 hr of birth is unusual and should suggest hemolysis, concealed hemorrhage, or causes of conjugated (direct) hyperbilirubinemia.*
¶ *Jaundice suddenly appearing in the 2nd wk of life or continuing beyond the 2nd wk of life with significant hyperbilirubinemia levels to warrant therapy should be investigated in detail because it most probably is due to a serious underlying cause such as biliary atresia, galactosemia, hypothyroidism, or neonatal hepatitis.*

When identified, the underlying cause of the icterus should be treated—for example, antibiotics for septicemia. Physiologic factors that increase the risk of neurologic damage should also be treated (e.g., correction of acidosis).

PHOTOTHERAPY.

Clinical jaundice and indirect hyperbilirubinemia are reduced on exposure to a high intensity of light in the visible spectrum. Bilirubin absorbs light maximally in the blue range (420–470?nm). Nonetheless, broad-spectrum white, blue, special narrow-spectrum (super) blue, and less often, green lights have been effective in reducing bilirubin levels. Bilirubin in the skin absorbs light energy, which by photo-isomerization converts the toxic native unconjugated 4Z,15Z-bilirubin into the unconjugated configurational isomer 4Z,15E-bilirubin. The latter

is the product of a reversible reaction and is excreted in bile without any need for conjugation. Phototherapy also converts native bilirubin, by an irreversible reaction, to the structural isomer lumirubin, which is excreted by the kidneys in the unconjugated state.

The use of phototherapy has decreased the need for exchange transfusion in term and preterm infants with hemolytic and nonhemolytic jaundice. When indications for exchange transfusion are present, phototherapy should not be used as a substitute. However, phototherapy may reduce the need for repeated exchange transfusions in infants with hemolysis.

Phototherapy is indicated only after the presence of pathologic hyperbilirubinemia has been established. The basic cause or causes of the jaundice should be treated concomitantly. Phototherapy may be initiated at the bilirubin levels noted in Tables 91–2 and 91–3 . Prophylactic phototherapy in VLBW infants may prevent hyperbilirubinemia and may reduce the incidence of exchange transfusions. VLBW infants receiving phototherapy for 1–3 days have peak serum bilirubin concentrations about half those of untreated infants. In premature infants without significant hemolysis, serum bilirubin usually declines 1–3?mg/dL after 12–24?hr of conventional phototherapy, and peak levels may be decreased by 3–6?mg/dL. The

therapeutic effect depends on the light energy emitted in the effective range of wavelengths, the distance between the lights and the infant, and the amount of skin exposed, as well as the rate of hemolysis and in vivo metabolism and excretion of bilirubin. The commercial phototherapy units available vary considerably in spectral output and the intensity of radiation emitted; therefore, the dose can be accurately measured only at the skin surface. Dark skin does not reduce the efficacy of phototherapy.

Maximal intensive phototherapy should be used when indirect bilirubin levels approach those noted in Tables 91–2 and 91–3 . Such therapy includes “special blue” fluorescent tubes, placing the lamps within 15–20?cm of the infant, and placing a fiberoptic phototherapy blanket under the infant's back to increase the exposed surface area.

Conventional phototherapy is applied continuously, and the infant is turned frequently for maximal skin exposure. It should be discontinued as soon as the indirect bilirubin concentration has been reduced to levels considered safe in view of the infant's age and condition. Serum bilirubin levels and hematocrit should be monitored every 4–8?hr in infants with hemolytic disease or those with bilirubin levels near the range considered toxic for the individual infant. Others, particularly older infants, may be monitored at 12–24?hr intervals. Monitoring should continue for at least 24?hr after cessation of phototherapy in patients with hemolytic disease because unexpected rises in serum bilirubin sometimes occur and require further treatment. Skin color cannot be relied on for evaluating the effectiveness of phototherapy; the skin of babies exposed to light may appear to be almost without jaundice in the presence of marked hyperbilirubinemia.

The infant's eyes should be closed and adequately covered to prevent exposure to light. Excessive pressure from an eye bandage may injure the closed eyes, or the corneas may be excoriated if the eyes can be opened under the bandage. Body temperature should be monitored, and the infant should be shielded from bulb breakage. If feasible, irradiance should be measured directly and details of the exposure recorded (type and age of the bulbs, duration of exposure, distance from the light source to the infant, and so forth). In infants with hemolytic disease, care must be taken to not overlook developing anemia, which may require transfusion.

Complications of phototherapy include loose stools, erythematous macular rash, a purpuric rash associated with transient porphyrinemia, overheating and dehydration (increased insensible water loss, diarrhea), chilling from exposure of the infant, and bronze baby syndrome. Phototherapy is contraindicated in the presence of porphyria. Eye injury and nasal occlusion from the bandages are uncommon.

The term *bronze baby syndrome* refers to a dark grayish brown discoloration of the skin sometimes noted in infants undergoing phototherapy. Almost all infants observed with this syndrome have had a mixed type of hyperbilirubinemia with significant elevation of direct-reacting bilirubin and often with other evidence of obstructive liver disease. The discoloration may be due to photo-induced modification of porphyrins, which are often present during cholestatic jaundice and may last for many months.

Wide clinical experience suggests that long-term adverse biologic effects of phototherapy are absent, minimal, or unrecognized. However, those using phototherapy should remain alert to these possibilities and avoid any unnecessary use because untoward effects on DNA have been demonstrated in vitro.

EXCHANGE TRANSFUSION.

Exchange transfusion is performed if intensive phototherapy has failed to reduce bilirubin levels to a safe range and if the risk of kernicterus exceeds the risk of the procedure or the infant has signs of kernicterus. Potential complications from exchange transfusion are not trivial and include acidosis, electrolyte abnormalities, hypoglycemia, thrombocytopenia, volume overload, arrhythmias, NEC, infection, graft vs host disease, and death. This widely accepted treatment is repeated if necessary to keep indirect bilirubin levels in a safe range (see Tables 91–2 and 91–3). See Exchange Transfusion in Chapter 92 .

Various factors may affect the decision to perform an exchange transfusion in an individual patient. The appearance of clinical signs suggesting kernicterus is an indication for exchange transfusion at any level of serum bilirubin. A healthy full-term infant with physiologic or breast milk jaundice may tolerate a concentration slightly higher than 25?mg/dL with no apparent ill effect, whereas kernicterus may develop in a sick premature infant at a significantly lower level. A level approaching that considered critical for the individual infant may be an indication for exchange transfusion during the 1st day or two of life when a further rise is anticipated, but not on the 4th day in term infants or on the 7th day in premature infants, when an imminent fall may be anticipated as the hepatic conjugating mechanism becomes more effective.

OTHER THERAPIES.

Tin (Sn)-protoporphyrin (or tin-mesoporphyrin) administration has also been proposed for reduction of bilirubin levels. It may inhibit the conversion of biliverdin to bilirubin by heme oxygenase. A single intramuscular dose on the 1st day of life may reduce the need for phototherapy. Such therapy may be beneficial when jaundice is anticipated (G6PD deficiency) or when blood products are discouraged (Jehovah's Witness). In patients with hyperbilirubinemia, bilirubin levels may decline, but the effect is no greater than that achieved with phototherapy. Complications include transient erythema if the infant is receiving phototherapy. More data are needed on efficacy and toxicity before these compounds can be recommended as therapy for hyperbilirubinemia.

Intravenous immunoglobulin (500?mg/kg/dose over a 4?hr period), given q12?hr for 3 doses, is effective in reducing bilirubin levels in patients with Coombs-positive hemolytic anemia, presumably by reducing hemolysis.

Chapter 92 - Blood Disorders

Barbara J. Stoll
Robert M. Kliegman

92.1 Anemia in the Newborn Infant

Hemoglobin increases with advancing gestational age: at term, cord blood hemoglobin is 16.8?g/dL (14–20?g/dL); hemoglobin levels in very low birthweight (VLBW) infants are 1–2?g/dL below those at term (Fig. 92–1). Less than the normal range of hemoglobin for birthweight and postnatal age is defined as anemia (see Table 438–1 (Table Not Available)). A "physiologic" decrease in hemoglobin content is noticed at 8–12 wk in term infants (hemoglobin, 11?g/dL) and at about 6 wk in premature infants (7–10?g/dL).

Infants born by cesarean section may have a lower hematocrit (Hct) than do those born vaginally. *Anemia at birth* is manifested as pallor, heart failure, or shock (Fig. 92–2). It may be due to acute or chronic blood loss, hemolysis, or underproduction of erythrocytes. It is usually caused by hemolytic disease of the

Figure 92.1-1 Range (mean and 95% confidence limits) of hemoglobin concentration from 16 to 40 wk of gestational age from normal (zone I) fetuses obtained by cordocentesis (percutaneous umbilical blood sample). *Solid circles* depict maternal red blood cell isoimmunization; *open circles* indicate hemoglobin levels in fetuses with ultrasonographic evidence of hydrops (zone III). (From Soothill P: Cordocentesis: Role in assessment of fetal condition. *Clin Perinatol* 1989;16:755.)

newborn but may also be a result of tearing or cutting of the umbilical cord during delivery, abnormal cord insertion, communicating placental vessels, placenta previa or abruptio, nuchal cord, incision into the placenta, internal hemorrhage (liver, spleen, or intracranial), a-thalassemia, congenital parvovirus infection or hypoplastic anemia, and twin-twin transfusion in monozygotic twins with arteriovenous placental connections (Chapter 86).

Transplacental hemorrhage with bleeding from the fetal into the maternal circulation has been reported in 5–15% of pregnancies, but unless severe, it is not usually sufficient to cause clinically apparent anemia at birth. The cause of transplacental hemorrhage is not clear, but its occurrence has been proved by demonstrating significant amounts of fetal hemoglobin and red blood cells (RBCs) in maternal blood on the day of delivery by the Kleihauer-Betke test or by flow cytometry methods to detect fetal cells in maternal blood. If the infant has severe anemia with heart failure, emergency exchange transfusion to restore Hct and oxygen-carrying capacity may be needed.

Acute blood loss usually results in severe distress at birth, initially with a normal hemoglobin level, no hepatosplenomegaly, and early onset of shock. In contrast, chronic blood loss in utero produces marked pallor, less distress, a low hemoglobin level with microcytic indices, and if severe, heart failure.

Anemia appearing in the first few days after birth is also most frequently a result of hemolytic disease of the newborn. Other causes are hemorrhagic disease of the newborn, bleeding from an improperly tied or clamped umbilical cord, large cephalohematoma, intracranial hemorrhage, or subcapsular bleeding from rupture of the liver, spleen, adrenals, or kidneys. Rapid decreases in hemoglobin or Hct values during the first few days of life may be the initial clue to these conditions.

Later in the neonatal period, delayed anemia may develop as a result of hemolytic disease of the newborn, with or without exchange transfusion or phototherapy. Congenital hemolytic anemia (spherocytosis) occasionally appears during the 1st mo of life, and hereditary nonspherocytic hemolytic anemia has been described during the neonatal period secondary to deficiency of glucose-6-phosphate dehydrogenase (G6PD) and

Figure 92.1-2 Diagnostic approach to anemia in newborn infants. MCV = mean corpuscular volume; G6PD = glucose-6-phosphate dehydrogenase. (From Blanchette V, Zipursky A: Assessment of anemia in newborn infants. *Clin Perinatol* 1984;11:489.)

pyruvate kinase. Bleeding from hemangiomas of the upper gastrointestinal tract or from ulcers caused by aberrant gastric mucosa in a Meckel diverticulum or duplication is a rare source of anemia in newborns. Repeated blood sampling of infants requiring frequent monitoring of blood gas and chemistry parameters is a common cause of anemia. Deficiency of minerals such as copper may cause anemia in infants maintained on total parenteral nutrition.

Anemia of prematurity occurs in low-birthweight infants 1–3 mo after birth, is associated with hemoglobin levels below 7–10?g/dL, and is clinically manifested as pallor, apnea, poor weight gain, decreased activity, tachypnea, tachycardia, and feeding problems. Repeated phlebotomy for blood tests, shortened RBC survival, rapid growth, and the physiologic effects of the transition from fetal (low Pa_{O_2} and hemoglobin saturation) to neonatal life (high Pa_{O_2} and hemoglobin saturation) contribute to anemia of prematurity. The oxygen available to neonatal tissue is lower than that in adults, but a neonate's erythropoietin response is attenuated for the degree of anemia, and as a result, hemoglobin and reticulocyte levels are low. In VLBW infants, delayed clamping of the umbilical cord with the infant held below the level of the placenta may enhance placental-infant transfusion and reduce postnatal transfusion needs. This maneuver should not delay any needed resuscitation and

may lead to hyperviscosity.

Treatment of neonatal anemia by blood transfusion depends on the severity of symptoms, the hemoglobin level, and the presence of co-morbid diseases (bronchopulmonary dysplasia, cyanotic congenital heart disease, hyaline membrane disease) that interfere with oxygen delivery. The need for treatment with blood should be balanced against the risks of transfusion, including hemolytic transfusion reactions, exposure to blood product preservatives and other potential toxins, volume overload, possible increased risk of retinopathy of prematurity and necrotizing enterocolitis, graft vs host reaction, and transfusion-acquired infection (cytomegalovirus [CMV], HIV, hepatitis B and C). The risk of CMV infection can be almost eliminated by the use of CMV antibody–negative blood and the highly recommended, irradiated white blood cell–poor blood; the risk of acquiring HIV and hepatitis B and C viruses is reduced but not eliminated by antibody screening of donated blood. Blood banking techniques that limit multiple donor exposure should be encouraged. Variations in blood transfusion practices among different neonatal intensive care units have been documented. Although transfusion guidelines for preterm infants have been proposed (Table 92–1), they have not been subjected to rigorous clinical study. Nonetheless, these guidelines have led to a decline in the number of unnecessary transfusions.

Asymptomatic full-term infants with a hemoglobin level of 10?g/dL may be monitored, whereas symptomatic neonates born after abruptio placentae or with severe hemolytic disease of the newborn warrant immediate transfusion. Preterm infants who have repeated episodes of apnea and bradycardia despite

TABLE 92.1-1 -- **Transfusion Protocol**

Hct/Hgb	Respiratory Support and/or Symptoms	Transfusion Volume
Hct =35/Hgb =11	Infants requiring moderate or significant mechanical ventilation (MAP >8?cm H_2O and F_{io_2} >0.4)	15?mL /kg PRBC* over period of 2–4?hr
Hct =30/Hgb =10	Infants requiring minimal respiratory support (any mechanical ventilation or endotracheal/nasal CPAP >6?cm H_2O and F_{io_2} =0.4)	15?mL /kg PRBCs over period of 2–4?hr
Hct =25/Hgb =8	Infants not requiring mechanical ventilation but who are receiving supplemental O_2 or CPAP with an F_{io_2} =0.4 and in whom 1 or more of the following is present: • =24?hr of tachycardia (HR > 180) or tachypnea (RR > 80) • An increased oxygen requirement from the previous 48?hr, defined as a =4-fold increase in nasal canula flow (i.e., 0.25 to 1?L/min) or an increase in nasal CPAP =20% from the previous 48?hr (i.e., 5 to 6?cm H_2O) • Weight gain <10?g/kg/day over the previous 4 days while receiving =100?kcal/kg/day • An increase in episodes of apnea and bradycardia (>9 episodes in a 24-hr period or =2 episodes in 24?hr requiring bag and mask ventilation) while receiving therapeutic doses of methylxanthines • Undergoing surgery	20?mL /kg PRBCs over period of 2–4?hr (divide into 2–10?mL/kg volumes if fluid sensitive)
Hct =20/Hgb =7	Asymptomatic and an absolute reticulocyte count <100 000 cells/µL	20?mL /kg PRBCs over period of 2–4?hr (2–10?mL/kg volumes)

Hct = hematocrit; Hgb = hemoglobin; MAP = mean airway pressure; F_{io_2} = fractional inspired oxygen; PRBC = packed red blood cells; CPAP = continuous positive airway pressure; HR = heart rate; RR = respiratory rate*. RBC should be irradiated prior to transfusion.

From Ohls RK, Ehrenkranz RA, Wright LL, et al: Effects of early erythropoietin therapy on the transfusion requirements of preterm infants below 1250 grams birth weight: A multicenter, randomized, controlled trial. Pediatrics 2001; 108:934–42.

theophylline therapy and a hemoglobin level of 8?g/dL or lower may benefit from RBC transfusion. In addition, infants with hyaline membrane disease or severe chronic lung disease may need hemoglobin levels of 12–14?g/dL to improve oxygen delivery. No transfusion is needed to replace blood removed for testing or for mild asymptomatic anemia. Asymptomatic neonates with reticulocytopenia and hemoglobin levels of 7?g/dL or lower may require transfusion; if a transfusion is not provided, close observation is essential. Packed RBC transfusion (10–20?mL/kg) is given at a rate of 2–3?mL/kg/hr to raise the hemoglobin concentration; 2?mL/kg raises the hemoglobin level 0.5–1?g/dL. Hemorrhage should be treated with whole blood if available; alternatively, fluid resuscitation is initiated and followed by packed RBC transfusion.

Recombinant human erythropoietin (r-HuEPO) has been used to prevent or treat chronic anemia associated with prematurity, bronchopulmonary dysplasia, and the hyporegenerative anemia of erythroblastosis fetalis. Anemia of prematurity is associated with abnormally low endogenous levels of serum erythropoietin but with r-HuEPO–responsive erythrocyte progenitor cells. Therapy with r-HuEPO may be

given by the intravenous or subcutaneous routes and must be supplemented with oral iron and possibly vitamin E. Doses and regimens vary. Treatment with erythropoietin and iron does not have a major impact on transfusion requirements, and therefore routine use of erythropoietin in VLBW infants is not recommended.

92.2 Hemolytic Disease of the Newborn (Erythroblastosis Fetalis)

Erythroblastosis fetalis is caused by the transplacental passage of maternal antibody active against RBC antigens of the infant and is characterized by an increased rate of RBC destruction. It continues to be an important cause of anemia and jaundice in newborn infants despite the development of a method of preventing maternal isoimmunization by Rh antigens. Although more than 60 different RBC antigens capable of eliciting an antibody response in a suitable recipient have been identified, significant disease is associated primarily with the D antigen of the Rh group and with incompatibility of ABO factors. Rarely, hemolytic disease may be caused by C or E antigens or by other RBC antigens such as C^W , C^X , D^U , K (Kell), M, Duffy, S, P, MNS, Xg, Lutheran, Diego, and Kidd. Anti-Lewis antibodies do not cause disease.

HEMOLYTIC DISEASE OF THE NEWBORN CAUSED BY RH INCOMPATIBILITY

The Rh antigenic determinants are genetically transmitted from each parent and determine the Rh type and direct the production of a number of blood group factors (C, c, D, d, E, and e). Each factor can elicit a specific antibody response under suitable conditions; 90% are due to D antigen and the remainder to C or E.

Pathogenesis.

Isoimmune hemolytic disease from D antigen is approximately three times more frequent in white persons than blacks. When Rh-positive blood is infused into an Rh-negative woman through error or when small quantities (usually more than 1?mL) of Rh-positive fetal blood containing D antigen inherited from an Rh-positive father enter the maternal circulation during pregnancy, with spontaneous or induced abortion, or at delivery, antibody formation against D antigen may be induced in the unsensitized Rh-negative recipient mother. Once sensitization has taken place, considerably smaller doses of antigen can stimulate an increase in antibody titer. Initially, a rise in IgM antibody occurs, which is later replaced by IgG antibody; the latter readily crosses the placenta and causes hemolytic manifestations.

Hemolytic disease rarely occurs during a first pregnancy because transfusions of Rh-positive fetal blood into an Rh-negative mother tend to occur near the time of delivery, too late for the mother to become sensitized and transmit antibody to her infant before delivery. The fact that 55% of Rh-positive fathers are heterozygous (D/d) and may have Rh-negative offspring and that fetal-to-maternal transfusion occurs in only 50% of pregnancies reduces the chance of sensitization, as does small family size, in which the opportunities for its occurrence are reduced. Finally, the capacity of Rh-negative women to form antibodies is variable, some producing low titers even after adequate antigenic challenge. Thus, the overall incidence of isoimmunization of Rh-negative mothers at risk is low, with antibody to D detected in less than 10% of those studied, even after five or more pregnancies; only about 5% ever have babies with hemolytic disease.

When the mother and fetus are also incompatible with respect to group A or B, the mother is partially protected against sensitization by the rapid removal of Rh-positive cells from her circulation by her pre-existing anti-A or anti-B, which are IgM antibodies and do not cross the placenta. Once a mother has been sensitized, her infant is likely to have hemolytic disease. The severity of Rh illness tends to worsen with successive

pregnancies. The possibility that the first affected infant after sensitization may represent the end of the mother's childbearing potential for Rh-positive infants argues urgently for the prevention of sensitization when possible. Such prevention consists of the injection of anti-D gamma globulin (RhoGAM) into the mother immediately after the delivery of each Rh-positive infant (see later).

Clinical Manifestations.

A wide spectrum of hemolytic disease occurs in affected infants born to sensitized mothers, depending on the nature of the individual immune response. The severity of the disease may range from only laboratory evidence of mild hemolysis (15% of cases) to severe anemia with compensatory hyperplasia of erythropoietic tissue leading to massive enlargement of the liver and spleen. When the compensatory capacity of the hematopoietic system is exceeded, profound anemia occurs and results in pallor, signs of cardiac decompensation (cardiomegaly, respiratory distress), massive anasarca, and circulatory collapse. This clinical picture of excessive abnormal fluid in two or more fetal compartments (skin, pleura, pericardium, placenta, peritoneum, amniotic fluid), termed *hydrops fetalis,* frequently results in death in utero or shortly after birth. With the use of RhoGAM to prevent Rh sensitization, nonimmune (nonhemolytic) conditions are more frequent causes of hydrops (Table 92–2). The severity of hydrops is related to the

TABLE 92.2-2 -- **Etiology of Hydrops Fetalis*** *The incidence of nonimmune (nonhemolytic) hydrops fetalis is 1/2,000–1/3,500 births.*

Category	Disorders	Category	Disorders
Anemia	Immune (Rh, Kell) hemolysis	Teratomas	Choriocarcinoma
	a-Thalassemia		Sacrococcygeal teratoma
	Red blood cell enzyme deficiencies (G6PD)	Tumors and storage diseases	Neuroblastoma
	Fetomaternal hemorrhage		Hepatoblastoma
	Donor in twin-to-twin transfusion		Gaucher disease

Cardiac dysrhythmias	Supraventricular tachycardia		Niemann-Pick disease
	Atrial flutter		Mucolipidosis
	Congenital heart block		GM_1 gangliosidosis
Structural heart lesions	Premature closure of foramen ovale		Mucopolysaccharidosis
	Tricuspid insufficiency	Chromosome abnormalities	Trisomy 13, 15, 16, 18, 21
	Hypoplastic left heart		XX/XY, 45XO
	Endocardial cushion defect		Partial duplication of chromosome 11, 15, 17, 18
	Cardiomyopathy		Partial deletion of chromosome 13, 18
	Endocardial fibroelastosis		Triploidy
	Tuberous sclerosis with cardiac rhabdomyoma		Tetraploidy
	Pericardial teratoma	Bone diseases	Osteogenesis imperfecta
Vascular	Chorioangioma of placenta, chorionic vessels, or umbilical vessels		Asphyxiating thoracic dystrophy
			Skeletal dysplasias
	Umbilical artery aneurysm	Congenital infections	Cytomegalovirus
	Angiomyxoma of umbilical cord		Parvovirus
	True knot of umbilical cord		Rubella
	Hepatic hemangioma		Toxoplasmosis
	Cerebral arteriovenous malformation (aneurysm of vein of Galen)		Syphilis
			Leptospirosis
	Angiosteohypertrophy (Klippel-TrÈnaunay syndrome)		Chagas disease
	Thrombosis of renal or umbilical vein or inferior vena cava	Others	Bowel obstruction with perforation and meconium peritonitis, volvulus
	Recipient in twin-to-twin transfusion		Hepatic fibrosis

Lymphatic	Lymphangiectasia		Beckwith-Wiedemann syndrome
	Cystic hygroma		Prune-belly syndrome
	Chylothorax, chylous ascites		Congenital nephrosis
	Noonan syndrome		Infant of a diabetic mother
	Multiple pterygium syndrome		Myotonic dystrophy
Central nervous system	Absent corpus callosum		Neu-Laxova syndrome
	Encephalocele		Maternal therapy with indomethacin
	Intracranial hemorrhage	Idiopathic	Multiple congenital anomaly syndromes
	Holoprosencephaly		
Thoracic lesions	Cystic adenomatoid malformation of lung		
	Mediastinal teratoma		
	Diaphragmatic hernia		
	Sequestered lung

Modified from Phibbs R: In Polin N, Fox W (editors): Fetal and Neonatal Physiology, 2nd ed. Philadelphia, WB Saunders, 1998.

level of anemia and the degree of reduction in serum albumin (oncotic pressure), which is due in part to hepatic dysfunction. Alternatively, heart failure may increase right heart pressure, with the subsequent development of edema and ascites. Failure to initiate spontaneous effective ventilation because of pulmonary edema or bilateral pleural effusions results in birth asphyxia; after successful resuscitation, severe respiratory distress may develop. Petechiae, purpura, and thrombocytopenia may also be present in severe cases as a result of decreased platelet production or the presence of concurrent disseminated intravascular coagulation.

Jaundice may be absent at birth because of placental clearance of lipid-soluble unconjugated bilirubin, but in severe cases, bilirubin pigments stain the amniotic fluid, cord, and vernix caseosa yellow. Jaundice is generally evident on the 1st day of life because the infant's bilirubin-conjugating and excretory systems are unable to cope with the load resulting from massive hemolysis. Indirect-reacting bilirubin therefore accumulates postnatally and may rapidly reach extremely high levels and present a significant risk of bilirubin encephalopathy. The risk of kernicterus developing from hemolytic disease is greater than from comparable nonhemolytic hyperbilirubinemia, although the risk in an individual patient may be affected by other complications (e.g., anoxia, acidosis). Hypoglycemia occurs frequently in infants with

severe isoimmune hemolytic disease and

may be related to hyperinsulinism and hypertrophy of the pancreatic islet cells in these infants.

Infants born after intrauterine transfusion for prenatally diagnosed erythroblastosis may be severely affected because the indications for transfusion are evidence of already severe disease in utero (e.g., hydrops, fetal anemia). Such infants usually have very high (but extremely variable) cord levels of bilirubin, which reflects the severity of the hemolysis and its effects on hepatic function. Infants treated with intra-umbilical vein transfusions in utero may also have a benign postnatal course if the anemia and hydrops resolve before birth. Anemia from continuing hemolysis may be masked by the previous intrauterine transfusion, and the clinical manifestations of erythroblastosis may be superimposed on various degrees of immaturity resulting from spontaneous or induced premature delivery.

Laboratory Data.

Before treatment, the direct Coombs test is usually positive, and anemia is generally present. The cord blood hemoglobin content varies and is usually proportional to the severity of the disease; with hydrops fetalis it may be as low as 3–4?g/dL. Alternatively, despite hemolysis, it may be within the normal range because of compensatory bone marrow and extramedullary hematopoiesis. The blood smear typically shows polychromasia and a marked increase in nucleated RBCs. The reticulocyte count is increased. The white blood cell count is usually normal but may be elevated; thrombocytopenia may develop in severe cases. Cord bilirubin is generally between 3 and 5?mg/dL; direct-reacting (conjugated) bilirubin may be substantially elevated. Indirect-reacting bilirubin rises rapidly to high levels in the 1st 6?hr of life.

After intrauterine transfusions, cord blood may show a normal hemoglobin concentration, negative direct Coombs test, predominantly type O Rh-negative adult RBCs, and a relatively normal smear. Marked elevation of both indirect- and direct-reacting bilirubin levels has been reported in these infants.

Diagnosis.

Definitive diagnosis of erythroblastosis fetalis requires demonstration of blood group incompatibility and corresponding antibody bound to the infant's RBCs.

ANTENATAL DIAGNOSIS.

In Rh-negative women, a history of previous transfusions, abortion, or pregnancy should suggest the possibility of sensitization. Expectant parents' blood types should be tested for potential incompatibility, and the maternal titer of IgG antibodies to D antigen should be assayed at 12–16, 28–32, and 36 wk. Fetal Rh status may be determined by isolating fetal cells or fetal DNA (plasma) from the maternal circulation or by amniocentesis and polymerase chain reaction with primers to the Rh gene. The presence of measurable antibody titer at the beginning of pregnancy, a rapid rise in titer, or a titer of 1:64 or greater suggests significant hemolytic disease, although the exact titer correlates poorly with the severity of disease. If a mother is found to have antibody against D antigen at a titer of 1:16 or greater at any time during a subsequent pregnancy, the severity of fetal disease should be monitored by amniocentesis, percutaneous umbilical blood sampling (PUBS), and ultrasonography. If the mother has a history of a previously affected infant or a stillbirth, an Rh-positive infant is usually equally or more severely affected than the previous infant, and the severity of disease in the fetus should be monitored.

Assessment of the fetus may require information obtained from ultrasonography, amniocentesis, and PUBS. Real-time ultrasonography is used to detect the progression of disease, with hydrops defined as skin or scalp edema, pleural or pericardial effusions, and ascites. Early ultrasonographic signs of hydrops include organomegaly (liver, spleen, heart), the double–bowel wall sign (bowel edema), and placental thickening. Progression to polyhydramnios, ascites, pleural or pericardial effusions, and skin or scalp edema may then follow. If pleural effusions precede ascites and hydrops by a significant length of time, causes other than fetal anemia should be suspected (see Table 92–2). Extramedullary hematopoiesis and, less so, hepatic congestion compress the intrahepatic vessels and produce venous stasis with portal hypertension, hepatocellular dysfunction, and decreased albumin synthesis.

Hydrops is present when fetal hemoglobin is less than 5?g/dL, frequent when under 7?g/dL, and variable between 7 and 9?g/dL. Real-time ultrasonography predicts fetal well-being by the biophysical profile (see Table 85–2), whereas Doppler ultrasonography assesses fetal distress by demonstrating increased vascular resistance. In pregnancies with ultrasonographic evidence of hemolysis (hepatosplenomegaly), early or late hydrops, or fetal distress, amniocentesis or PUBS should be performed.

Amniocentesis is used to assess fetal hemolysis. Hemolysis of fetal RBCs produces hyperbilirubinemia before the onset of severe anemia. Bilirubin is cleared by the placenta, but a significant proportion enters the amniotic fluid and can be measured by spectrophotometry. Amniocentesis is performed if the mother has evidence of sensitization (titer of 1:16), if the father is Rh positive, or if ultrasonographic signs of hemolysis, hydrops, or distress are present. Ultrasonographically guided transabdominal aspiration of amniotic fluid may be performed as early as 18–20 wk of gestation. Spectrophotometric scanning of amniotic fluid wavelengths demonstrates a positive optical density (OD) deviation of absorption for bilirubin from normal at 450?nm (Fig. 92–3 (Figure Not Available)). The OD_{450} is a reflection of fetal bilirubin levels and thus hemolysis and indicates the severity of anemia and the risk of intrauterine death. With maturity, the level of amniotic fluid bilirubin normally declines, so fetal risk is assessed during gestation in terms of three relative, but declining zones of OD_{450} , with zone III representing the highest risk. However, some fetuses in zone III do not have life-threatening fetal anemia and thus do not require intrauterine transfusion. If the OD_{450} is in zone III or if hydrops or other signs suggesting fetal anemia are present, PUBS should be performed to determine fetal hemoglobin levels and packed RBCs transfused in those with serious anemia (Hct of 25–30%). Amniocentesis and cordocentesis are invasive procedures with risks to both the fetus and mother, including fetal death, fetal bleeding, fetal bradycardia,

worsening of alloimmunization, premature rupture of membranes,

Figure 92.2-3 (Figure Not Available) Optical density of amniotic fluid plotted against weeks of gestation. Severely affected infants are managed by intrauterine transfusion before 32–33 wk and delivery thereafter. A moderately affected fetus warrants repeated amniocentesis, monitoring by cardiotocography, and delivery at 34–37 wk. A mildly affected fetus warrants delivery at 37–40 wk. (From Blood group incompatibility. In Beischer NA, Mackay EV, Colditz PB [editors]: *Obstetrics and the Newborn,* 3rd ed. Philadelphia, WB Saunders, 1997.)

preterm labor, and chorioamnionitis. Noninvasive measurements to detect fetal anemia are desirable. In fetuses without hydrops, moderate to severe anemia can be detected noninvasively by demonstration of an increase in the peak velocity of systolic blood flow in the middle cerebral artery by Doppler ultrasound. This and other noninvasive techniques deserve further study.

POSTNATAL DIAGNOSIS.

Immediately after the birth of any infant to an Rh-negative woman, blood from the umbilical cord or from the infant should be examined for ABO blood group, Rh type, Hct and hemoglobin, and reaction of the direct Coombs test. If the Coombs test is positive, a baseline serum bilirubin level should be measured, and a commercially available RBC panel should be used to identify RBC antibodies present in the mother's serum, both tests being performed not only to establish the diagnosis but also to ensure selection of the most compatible blood for exchange transfusion should it be necessary. The direct Coombs test is usually strongly positive in clinically affected infants and may remain so for a few days up to several months.

Treatment.

The main goals of therapy are to (1) prevent intrauterine or extrauterine death from severe anemia and hypoxia and (2) avoid neurotoxicity from hyperbilirubinemia.

TREATMENT OF AN UNBORN INFANT.

Survival of severely affected fetuses has been improved by the use of ultrasonographic and amniotic fluid analysis to identify the need for in utero transfusion. Intrauterine transfusion into the fetal peritoneal cavity is being replaced by direct intravascular (umbilical vein) transfusion of packed RBCs. Hydrops or fetal anemia (Hct <30%) is an indication for umbilical vein transfusion in infants with pulmonary immaturity (see Fig. 92–1). Intravascular transfusion is facilitated by maternal and hence fetal sedation with diazepam and by fetal paralysis with pancuronium. Packed RBCs are given by slow-push infusion after cross matching with the mother's serum. The cells should be obtained from a CMV-negative donor and irradiated to kill lymphocytes to avoid graft vs host disease. Transfusions should achieve a post-transfusion Hct of 45–55% and can be repeated every 3–5 wk. Indications for delivery include pulmonary maturity, fetal distress, complications of PUBS, or 35–37 wk of gestation.

TREATMENT OF A LIVEBORN INFANT.

The birth should be attended by a physician skilled in neonatal resuscitation. Fresh, low-titer, group O, irradiated Rh-negative blood cross-matched against maternal serum should be immediately available. If clinical signs of severe hemolytic anemia (pallor, hepatosplenomegaly, edema, petechiae, or ascites) are evident at birth, immediate resuscitation and supportive therapy, temperature stabilization, and monitoring before proceeding with exchange transfusion may save some severely affected infants. Such therapy should include correction of acidosis with 1–2?mEq/kg of sodium bicarbonate; a small transfusion of compatible packed RBCs to correct anemia; volume expansion for hypotension, especially in those with hydrops; and provision of assisted ventilation for respiratory failure.

EXCHANGE TRANSFUSION.

When an infant's clinical condition at birth does not require an immediate full or partial exchange transfusion, the decision to perform one should be based on a judgment that the infant has a high risk of rapid development of a dangerous degree of anemia or hyperbilirubinemia. Cord hemoglobin of 10?g/dL or less and bilirubin of 5?mg/dL or more suggest severe hemolysis but inconsistently predict the need for exchange transfusion. Some physicians consider previous kernicterus or severe erythroblastosis in a sibling, reticulocyte counts greater than 15%, and prematurity to be additional factors supporting a decision for early exchange transfusion. Intrauterine, intravascular transfusions have decreased the need for exchange transfusion.

The hemoglobin concentration, Hct, and serum bilirubin level should be measured at 4–6?hr intervals initially, with extension to longer intervals if and as the rate of change diminishes. The decision to perform an exchange transfusion is based on the likelihood that the trend of bilirubin levels plotted against hours of age indicates that serum bilirubin will reach the levels indicated in Tables 91–2 and 91–3 . Term infants with levels of 20?mg/dL or higher have an increased risk of kernicterus. Ordinary transfusions of compatible Rh-negative irradiated RBCs may be necessary to correct anemia at any stage of the disease up to 6–8 wk of age, when the infant's own blood-forming mechanism may be expected to take over. Weekly determinations of hemoglobin or Hct should be done until a spontaneous rise has been demonstrated.

Careful monitoring of the serum bilirubin level is essential until a falling trend has been demonstrated in the absence of phototherapy (Chapter 91.4). Even then, an occasional infant, particularly if premature, may experience an unpredicted significant rise in serum bilirubin as late as the 7th day of life. Attempts to predict the attainment of dangerously high levels of serum bilirubin based on observed levels exceeding 6?mg/dL in the 1st 6?hr or 10?mg/dL in the 2nd 6?hr of life or on rates of rise exceeding 0.5–1.0?mg/dL/hr can be unreliable. Measurement of unbound bilirubin may be a more sensitive predictor of the risk associated with hyperbilirubinemia.

Blood for exchange transfusion should be as fresh as possible. Heparin or citrate-phosphate-dextrose-adenine solution may be used as an anticoagulant. If the blood is obtained before delivery, it should be taken from a type O, Rh-negative

donor with a low titer of anti-A and anti-B antibodies and should be compatible with the mother's serum by the indirect Coombs test. After delivery, blood should be obtained from an Rh-negative donor whose cells are compatible with both the infant's and the mother's serum; when possible, type O donor cells are generally used, but cells of the infant's ABO blood type may be used when the mother has the same type. A complete cross match, including an indirect Coombs test, should be performed before the 2nd and subsequent transfusions. Blood should be gradually warmed and maintained at a temperature between 35 and 37℃ throughout the exchange transfusion. It should be kept well mixed by gentle squeezing or agitation of the bag to avoid sedimentation; otherwise, the use of supernatant serum with a low RBC count at the end of the exchange will leave the infant anemic. Whole blood or packed irradiated RBCs reconstituted with fresh frozen plasma to an Hct of 40% should be used. The infant's stomach should be emptied before transfusion to prevent aspiration, and body temperature should be maintained and vital signs monitored. A competent assistant should be present to help monitor, tally the volume of blood exchanged, and perform emergency procedures.

With strict aseptic technique, the umbilical vein is cannulated with a polyvinyl catheter to a distance no greater than 7?cm in a full-term infant. When free flow of blood is obtained, the catheter is usually in a large hepatic vein or the inferior vena cava. Alternatively, the exchange may be performed through peripheral arterial (drawn out) and venous (infused in) lines. The exchange should be carried out over a 45–60?min period, with aspiration of 20?mL of infant blood alternating with infusion of 20?mL of donor blood. Smaller aliquots (5–10?mL) may be indicated for sick and premature infants. The goal should be an isovolumetric exchange of approximately two blood volumes of the infant (2 × 85?mL/kg).

Infants with acidosis and hypoxia from respiratory distress, sepsis, or shock may be further compromised by the significant acute acid load contained in citrated blood, which usually has a pH between 7 and 7.2. The subsequent metabolism of citrate may result in metabolic alkalosis later if citrated blood is used. Fresh heparinized blood avoids this problem. During the exchange, blood pH and Pa_{O_2} should be serially monitored

---

because infants often become acidotic and hypoxic during exchange transfusions. Symptomatic hypoglycemia may occur before or during an exchange transfusion in moderately to severely affected infants; it may also occur 1–3?hr after exchange. Acute complications, noted in 5–10% of infants, include transient bradycardia with or without calcium infusion, cyanosis, transient vasospasm, thrombosis, apnea with bradycardia requiring resuscitation, and death. Infectious risks include CMV, HIV, and hepatitis. Necrotizing enterocolitis is a rare complication of exchange transfusion.

The risk of death from an exchange transfusion performed by an experienced physician is 0.3/100 procedures. However, with the decreasing use of this procedure because of the use of phototherapy and prevention of sensitization, the general level of physician competence is decreasing. Thus, it is best if this procedure is performed in experienced neonatal referral centers.

After exchange transfusion, the bilirubin level must be determined at frequent intervals (every 4–8?hr) because bilirubin may rebound 40–50% within hours. Repeated exchange transfusions should be carried out to keep the indirect fraction from exceeding the levels indicated in Table 91–2 for preterm infants and 20?mg/dL for term infants. Symptoms suggestive of kernicterus are mandatory indications for exchange transfusion at any time.

LATE COMPLICATIONS.

Infants who have hemolytic disease or who have had an exchange or an intrauterine transfusion must be observed carefully for the development of anemia and cholestasis. Late anemia may be hemolytic or hyporegenerative. Treatment with supplemental iron, erythropoietin, or blood transfusion may be indicated. A mild graft vs host reaction may be manifested as diarrhea, rash, hepatitis, or eosinophilia.

Inspissated bile syndrome refers to the rare occurrence of persistent icterus in association with significant elevations in direct and indirect bilirubin in infants with hemolytic disease. The cause is unclear, but the jaundice clears spontaneously within a few weeks or months.

Portal vein thrombosis and *portal hypertension* may occur in children who have been subjected to exchange transfusion as newborn infants. It is probably associated with prolonged, traumatic, or septic umbilical vein catheterization.

PREVENTION OF RH SENSITIZATION.

The risk of initial sensitization of Rh-negative mothers has been reduced from between 10 and 20% to less than 1% by the intramuscular injection of 300 μg of human anti-D globulin (1?mL of RhoGAM) within 72?hr of delivery of an Rh-positive infant, ectopic pregnancy, abdominal trauma in pregnancy, amniocentesis, chorionic villus biopsy, or abortion. This quantity is sufficient to eliminate approximately 10?mL of potentially antigenic fetal cells from the maternal circulation. Large fetal-to-maternal transfers of blood may require proportionately more RhoGAM. RhoGAM administered at 28–32 wk and again at birth (40 wk) is more effective than a single dose. The use of this technique, combined with improved methods of detecting maternal sensitization and measuring the extent of fetal-to-maternal transfusion, plus the use of fewer obstetric procedures that increase the risk of such fetal-to-maternal bleeding (version, manual separation of the placenta, and so on), should further reduce the incidence of erythroblastosis fetalis.

HEMOLYTIC DISEASE OF THE NEWBORN CAUSED BY A AND B INCOMPATIBILITY

ABO incompatibility is the most common cause of hemolytic disease of the newborn. Approximately 15% of live births are at risk, but manifestations of disease develop in only 0.3–2.2%. Major blood group incompatibility between the mother and fetus generally results in milder disease than Rh incompatibility does. Maternal antibody may be formed against B cells if the mother is type A or against A cells if the mother is type B. However, usually, the mother is type O and the infant is type A or B.

Although ABO incompatibility occurs in 20–25% of pregnancies, hemolytic disease develops in only 10% of such offspring, and the infants are generally type A_1 , which is more antigenic than A_2 . Low antigenicity of the ABO factors in the fetus and newborn infant may account for the low incidence of severe ABO hemolytic disease relative to the incidence of incompatibility between the blood groups of the mother and child. Although antibodies against A and B factors occur without previous immunization ("natural" antibodies), they are ordinarily present in the IgM fraction of gamma globulin, which does not cross the placenta. However, univalent, incomplete (albumin active) antibodies to A antigen may be present in the IgG fraction, which does cross the placenta, so A-O isoimmune hemolytic disease may be found in first-born infants. Mothers who have become immunized against A or B factors from a previous incompatible pregnancy also exhibit IgG antibody. These "immune" antibodies are the primary mediators in ABO isoimmune disease.

Clinical Manifestations.

Most cases are mild, with jaundice being the only clinical manifestation. The infant is not generally affected at birth; pallor is not present, and hydrops fetalis is extremely rare. The liver and spleen are not greatly enlarged, if at all. Jaundice usually appears during the 1st 24?hr. Rarely, it may become severe, and symptoms and signs of kernicterus develop rapidly.

Diagnosis.

A presumptive diagnosis is based on the presence of ABO incompatibility, a weakly to moderately positive direct Coombs test result, and spherocytes in the blood smear, which may at times suggest the presence of hereditary spherocytosis. Hyperbilirubinemia is often the only other laboratory abnormality. The hemoglobin level is usually normal but may be as low as 10–12?g/dL (100–120?g/L). Reticulocytes may be increased to 10–15%, with extensive polychromasia and increased numbers of nucleated RBCs. In 10–20% of affected infants, the unconjugated serum bilirubin level may reach 20?mg/dL or more unless phototherapy is administered.

Treatment.

Phototherapy may be effective in lowering serum bilirubin levels (Chapter 91.4). In rare severe cases, treatment is directed at correcting dangerous degrees of anemia or hyperbilirubinemia by exchange transfusions with type O blood of the same Rh type as the infant. Indications for this procedure are similar to those previously described for hemolytic disease caused by Rh incompatibility. Some infants with ABO hemolytic disease may require transfusion of packed RBCs at several weeks of age because of slowly progressive anemia. Post-discharge monitoring of hemoglobin/Hct is essential in newborns with ABO hemolytic disease.

OTHER FORMS OF HEMOLYTIC DISEASE

Blood group incompatibilities other than Rh or ABO (c, E, K, and so on) account for less than 5% of hemolytic disease of the newborn. The direct Coombs test is invariably positive, and exchange transfusion may be indicated for hyperbilirubinemia and anemia. Hemolytic disease, anemia, and hydrops fetalis as a result of anti-Kell antibodies are not predictable from the previous obstetric history, amniotic fluid OD_{450} bilirubin determinants, or the maternal antibody titer. Erythroid suppression may contribute to the anemia; PUBS is beneficial in actually measuring the fetal Hct.

Congenital infections such as cytomegalic inclusion disease, toxoplasmosis, rubella, and syphilis may be manifested as hemolytic anemia, jaundice, hepatosplenomegaly, and thrombocytopenia, but the direct Coombs test result is negative and these conditions usually have other distinguishing clinical findings. Homozygous a-thalassemia may be associated with severe

---

606

hemolytic anemia and a clinical picture resembling hydrops fetalis; it can be distinguished by a negative direct Coombs test result and characteristic clinical and laboratory findings (Chapter 454.9). Anemia and jaundice may occur in infancy from hereditary spherocytosis (Chapter 450) and, if untreated, can result in kernicterus. Hemolytic anemia producing jaundice in the 1st wk of life may also be secondary to congenital deficiencies in RBC enzymes, such as pyruvate kinase or G6PD.

92.3 Plethora in the Newborn Infant (Polycythemia) (See Chapters 458 and 459)

Plethora, a ruddy, deep red-purple appearance associated with a high Hct, is often due to polycythemia, defined as a central Hct of 65% or higher. Peripheral (heelstick) Hct values are higher than central values, whereas Coulter counter results are lower than Hct values determined by microcentrifugation. The incidence of neonatal polycythemia is increased at high altitude (5% in Denver vs 1.6% in Texas); in postmature (3%) vs term (1–2%) infants; in small for gestational age (8%) vs large for gestational age (3%) vs average for gestational age (1–2%) infants; during the 1st day of life (peak, 2–3?hr); in the recipient infant of a twin-twin transfusion; after delayed clamping of the umbilical cord; in infants of diabetic mothers; in trisomy 13, 18 or 21; in adrenogenital syndrome; in neonatal Graves disease; in hypothyroidism; and in Beckwith-Wiedemann syndrome. Infants of diabetic mothers and those with growth retardation may have been exposed to chronic fetal hypoxia, which stimulates erythropoietin production and increases RBC production.

Clinical manifestations include anorexia, lethargy, tachypnea, respiratory distress, feeding disturbances, hyperbilirubinemia, hypoglycemia, and thrombocytopenia. Severe complications include seizures, pulmonary hypertension, necrotizing enterocolitis, and renal failure. Many affected infants are asymptomatic. Hyperviscosity is present in most infants with central Hct values of 65% or higher and accounts for the symptoms of polycythemia. Hyperviscosity determined at constant shear rates (e.g., 11.5?sec^{-1}) is present when whole blood viscosity is above 18 cycles/sec. Hyperviscosity is accentuated because neonatal RBCs have decreased deformability and filterability, which predisposes to stasis in the microcirculation.

Treatment of symptomatic polycythemic newborns is partial exchange transfusion

(with normal saline). The Hct level (without measurement of viscosity) at which to perform a partial exchange transfusion in an asymptomatic infant is unclear. Partial exchange will lower the Hct and viscosity and improve acute symptoms. The volume to be exchanged is calculated from the following formula:

The long-term *prognosis* of polycythemic infants is unclear. Reported adverse outcomes include speech deficits, abnormal fine motor control, reduced IQ, school problems, and other neurologic abnormalities. It is thought that the underlying etiology (e.g., chronic intrauterine hypoxia) and hyperviscosity contribute to adverse outcomes. It is unclear whether partial exchange transfusion improves the long-term outcome.

92.4 Hemorrhage in the Newborn Infant

Hemorrhagic Disease of the Newborn.

A moderate decrease in factors II, VII, IX, and X normally occurs in all newborn infants by 48–72?hr after birth, with a gradual return to birth levels by 7–10 days of age. This transient deficiency of vitamin K–dependent factors is probably due to lack of free vitamin K in the mother and absence of the bacterial intestinal flora normally responsible for the synthesis of vitamin K. Rarely, in term infants and more frequently in premature infants, accentuation and prolongation of this deficiency between the 2nd and 7th days of life result in spontaneous and prolonged bleeding. Breast milk is a poor source of vitamin K, and hemorrhagic complications have appeared more frequently in breast-fed than in formula-fed infants. This classic form of hemorrhagic disease of the newborn, which is responsive to vitamin K therapy, must be distinguished from disseminated intravascular coagulopathy and from the more infrequent congenital deficiencies of one or more of the other factors that are unresponsive to vitamin K (Chapter 474). Early-onset life-threatening vitamin K deficiency–induced bleeding (onset from birth to 24?hr) also occurs if the mother has been treated with drugs (phenobarbital, phenytoin) that interfere with vitamin K function. Late onset (>1 wk) is often associated with vitamin K malabsorption, as noted in neonatal hepatitis or biliary atresia (Table 92–3).

Hemorrhagic disease of the newborn resulting from severe transient deficiencies in vitamin K–dependent factors is characterized by bleeding that tends to be gastrointestinal, nasal, subgaleal, intracranial, or due to circumcision. Prodromal or warning signs (mild bleeding) may occur before serious intracranial hemorrhage. The prothrombin time (PT), blood coagulation time, and partial thromboplastin time are prolonged, and levels of prothrombin (II) and factors VII, IX, and X are significantly decreased. Vitamin K facilitates post-transcriptional carboxylation of factors II, VII, IX, and X. In the absence of carboxylation, such factors form PIVKA (protein induced in vitamin K absence), which is a sensitive marker for vitamin K status. Bleeding time, fibrinogen, factors V and VIII, platelets, capillary fragility, and clot retraction are normal for maturity.

Intramuscular administration of 1?mg of vitamin K at the time of birth prevents the decrease in vitamin K–dependent factors in full-term infants, but it is not uniformly effective in the prophylaxis of hemorrhagic disease of the newborn in premature infants. The disease may be effectively treated with a slow intravenous infusion of 1–5?mg of vitamin K_1 , with improvement in coagulation defects and cessation of bleeding noted within a few hours. However, serious bleeding, particularly in premature infants or those with liver disease, may require a transfusion of fresh frozen plasma or whole blood. The mortality rate is low in treated patients.

A particularly severe form of deficiency of vitamin K–dependent coagulation factors has been reported in infants born to mothers receiving anticonvulsive medications (phenobarbital and phenytoin) during pregnancy. They may suffer severe bleeding, with onset within the 1st 24?hr of life; the bleeding is usually corrected by vitamin K_1 , although in some the response is poor or delayed. A PT should be obtained on cord blood and the infant given 1–2?mg of vitamin K intravenously. If the PT is greatly prolonged and fails to improve, 10?mL/kg of fresh frozen plasma should be administered.

The routine use of intramuscular vitamin K for prophylaxis in the United States has been safe and is not associated with an increased risk of childhood cancer or leukemia. Although oral vitamin K (birth, discharge, 3–4 wk: 1–2?mg) has been suggested as an alternative, the effectiveness of oral vitamin K has not been established and it cannot be recommended for routine therapy. The intramuscular route remains the method of choice.

Other forms of bleeding may be clinically indistinguishable from hemorrhagic disease of the newborn responsive to vitamin K, but they are neither prevented nor successfully treated with it. A clinical pattern identical to that of hemorrhagic disease of the newborn may also result from any of the congenital defects in blood coagulation (Chapters 468 , 469 , and 475). Hematomas, melena, and postcircumcision and umbilical cord bleeding may

TABLE 92.4-3 -- **Hemorrhagic Disease of the Newborn**

	Early Onset	**Classic Disease**	**Late Onset**
Age	0–24?hr	2–7 days	1–6 mo
Site of hemorrhage	Cephalohematoma	Gastrointestinal	Intracranial
	Subgaleal	Ear-nose-throat–mucosal	Gastrointestinal
	Intracranial	Intracranial	Cutaneous
	Gastrointestinal	Circumcision	Ear-nose-throat–mucosal
	Umbilicus	Cutaneous	Injection sites
	Intra-abdominal	Gastrointestinal	Thoracic
		Injection sites	

Etiology/risks	Maternal drugs (phenobarbital, phenytoin, warfarin, rifampin, isoniazid) that interfere with vitamin K	Vitamin K deficiency	Cholestasis—malabsorption of vitamin K (biliary atresia, cystic fibrosis, hepatitis)
		Breast-feeding	
			Abetalipoprotein deficiency
	Inherited coagulopathy		Idiopathic in Asian breast-fed infants
			Warfarin ingestion
Prevention	Possible vitamin K at birth or to mother (20?mg) before birth	Prevented by parenteral vitamin K at birth. Oral vitamin K regimens require repeated dosing over time	Prevented by parenteral and high-dose oral vitamin K during periods of malabsorption or cholestasis
	Avoid high-risk medications		
Incidence	Very rare	~2% if not given vitamin K	Dependent on primary disease

be present; only 5–35% of cases of factor VIII and IX deficiency become clinically apparent in the newborn period. Treatment of the rare congenital deficiencies of coagulation factors requires fresh frozen plasma or specific factor replacement.

Disseminated intravascular coagulopathy in newborn infants results in consumption of coagulation factors and bleeding. Affected infants are often premature; the clinical course is frequently characterized by hypoxia, acidosis, shock, hemangiomas, or infection. Treatment is directed at correcting the primary clinical problem, such as infection, and interrupting consumption and replacing clotting factors (Chapter 474).

Infants with central nervous system or other bleeding posing an *immediate threat to life* should receive fresh frozen plasma, vitamin K, and blood if needed as soon as possible after blood has been drawn for coagulation studies, which should include a determination of the number of platelets.

The so-called swallowed blood syndrome, in which blood or bloody stools are passed, usually on the 2nd or 3rd day of life, may be confused with hemorrhage from the gastrointestinal tract. The blood may be swallowed during delivery or from a fissure in the mother's nipple. Differentiation from gastrointestinal hemorrhage is based on the fact that the infant's blood contains mostly fetal hemoglobin, which is alkali resistant, whereas swallowed blood from a maternal source contains adult hemoglobin, which is promptly changed to alkaline hematin after the addition of alkali. Apt devised the following test for this differentiation: (1) Rinse a blood-stained diaper or some grossly bloody (red) stool with a suitable amount of water to obtain a distinctly pink supernatant hemoglobin solution. (2) Centrifuge the mixture and decant the supernatant solution. (3) To five parts of the supernatant fluid add one part of 0.25 N (1%) sodium hydroxide. Within 1–2?min a color reaction takes place: a yellow-brown color indicates that the blood is maternal in origin; a persistent pink indicates that it is from the infant. A control test with known adult or infant blood, or both, is advisable.

Widespread subcutaneous ecchymoses in premature infants at or immediately after birth are apparently a result of fragile superficial blood vessels rather than a coagulation defect. Administering vitamin K_1 to the mother during labor has no effect on the incidence of ecchymoses. Occasionally, an infant is born with petechiae or a generalized bluish suffusion limited to the face, head, and neck, probably as a result of venous obstruction by a nuchal cord or sudden increases in intrathoracic pressure during delivery. It may take 2–3 wk for such suffusions to disappear.

Neonatal Thrombocytopenic Purpura. See Chapter 475 .

Chapter 93 - Genitourinary System (see also Part XXIII)

Barbara J. Stoll
Robert M. Kliegman

Urinary tract anomalies (hydronephrosis, dysplasia, solitary kidney) are frequently identified by prenatal ultrasonography (see Table 85–5). After birth, the presence/extent of anomalies needs to be confirmed and followed by detailed evaluation and appropriate management. Follow-up of urinary anomalies diagnosed in utero requires renal ultrasonography after birth and again at 2 wk of life. For anomalies such as ureteropelvic junction obstruction and reflux, prenatal diagnosis provides the opportunity for early treatment to minimize functional deterioration and urinary tract infection.

One or both kidneys are often easily palpable in a newborn infant. When both are palpable and similar, infants usually do not have any particular diagnostic problems, but when only one kidney can be felt, a frequent impression is that it is larger than normal or is displaced by an intrinsic or extrinsic mass. Fetal lobulation may contribute to this impression. The problem usually resolves as the kidney becomes progressively less easily palpable during the early months of life. Because palpable enlargement or displacement of a kidney in a newborn may be due to hydronephrosis, neuroblastoma, mesoblastic nephroma, adrenal hemorrhage, or a cystic malformation, ultrasound examination is indicated.

Thrombosis of the Renal Vein. See Chapter 96 .

Circumcision (see Chapter 536).

Circumcision is the most common elective surgical procedure performed on newborn boys in the United States. The benefits relate to cultural or religious beliefs and to medical benefits and include a reduced incidence of balanitis, penile cancer, sexually transmitted diseases (including HIV), and urinary tract infections (in male infants). The risks are low (local infection, bleeding), but as with any surgical procedure, pain relief must be provided. Analgesia may include concentrated oral sucrose, a dorsal penile nerve block, or topical lidocaine-prilocaine cream.

Chapter 94 - The Umbilicus

Barbara J. Stoll
Robert M. Kliegman

Umbilical Cord.

The cord contains the two umbilical arteries, the vein, the rudimentary allantois, the remnant of the omphalomesenteric duct, and a gelatinous substance called Wharton jelly. The sheath of the umbilical cord is derived from the amnion. The muscular umbilical arteries contract readily, but the vein does not. The vein retains a fairly large lumen after birth. Abnormally short cords are associated with fetal hypotonia, long cords are at risk for true knots or wrapping around fetal parts (neck, arm), and straight untwisted cords are associated with fetal distress, anomalies, and intrauterine fetal demise.

When the cord sloughs after birth, portions of these structures remain in the base. The blood vessels are functionally closed, but anatomically patent for 10–20 days. The arteries become the lateral umbilical ligaments; the vein, the ligamentum teres; and the ductus venosus, the ligamentum venosum. During this interval, the umbilical vessels are potential portals of entry for infection. The umbilical cord usually sloughs within 2 wk. *Delayed separation of the cord*, after more than 1 mo, has been associated with neutrophil chemotactic defects and overwhelming bacterial infection (Chapter 120.2).

A **single umbilical artery** is present in about 5–10/1,000 births; the frequency is about 35–70/1,000 twin births. Approximately one third of infants with a single umbilical artery have congenital abnormalities, usually more than one, and many such infants are stillborn or die shortly after birth. Trisomy 18 is one of the more frequent abnormalities. Because many abnormalities are not apparent on gross physical examination, it is important that at every delivery the cut cord and the maternal and fetal surfaces of the placenta be inspected. The number of arteries present should be recorded as an aid to the early suspicion and identification of abnormalities in such infants. For infants with a single umbilical artery, some recommend renal ultrasonography.

Patency of the omphalomesenteric (vitelline) *duct* may be responsible for an intestinal fistula, prolapse of the bowel, a polyp (cyst), or a Meckel diverticulum (Chapter 312.2).

A *persistent urachus* (urachal cyst) is due to failure of closure of the allantoic duct and is associated with bladder outlet obstruction. Patency should be suspected if a clear, light yellow, urine-like fluid is being discharged from the umbilicus.

Congenital Omphalocele.

An omphalocele is a herniation or protrusion of the abdominal contents into the base of the umbilical cord. In contrast to the more common umbilical hernia, the sac is covered with peritoneum without overlying skin. The size of the sac that lies outside the abdominal cavity depends on its contents. Herniation of intestines into the cord occurs in about 1/5,000 births and herniation of liver and intestines in 1/10,000 births. The abdominal cavity is proportionately small because the impetus to grow and develop is deficient. Immediate surgical repair, before infection has taken place and before the tissues have been damaged by drying (saline-soaked sterile dressings should be applied immediately) or by rupture of the sac, is essential for survival. Mersilene or similar synthetic material may be used to cover the viscera if the sac has ruptured or if excessive mobilization of the skin would be necessary to cover the mass and its intact sac. The risk of associated congenital anomalies/syndromes, including Beckwith-Wiedemann syndrome (omphalocele, macrosomia, hypoglycemia), trisomies 13 and 18, and cardiac anomalies, is increased in patients with omphalocele.

Tumors.

Tumors of the umbilicus are rare and include angioma, enteroteratoma, dermoid cyst, myxosarcoma, and cysts of urachal or omphalomesenteric duct remnants.

Hemorrhage.

Hemorrhage from the umbilical cord may be due to trauma, inadequate ligation of the cord, or failure of normal thrombus formation. It may also indicate hemorrhagic disease of the newborn or other coagulopathies (factor XIII deficiency), septicemia, or local infection. The infant should be observed frequently during the first few days of life so that if hemorrhage does occur, it will be detected promptly.

Granuloma.

The umbilical cord usually dries and separates within 6–8 days after birth. The raw surface becomes covered by a thin layer of skin, scar tissue forms, and the wound is usually healed within 12–15 days. The presence of saprophytic organisms delays separation of the cord and increases the possibility of invasion by pathogenic organisms. Mild infection or incomplete epithelialization may result in a moist granulating area at the base of the cord with a slight mucoid or mucopurulent discharge. Good results are usually obtained by cleansing with alcohol several times

daily.

Persistence of granulation tissue at the base of the umbilicus is common. The tissue is soft, vascular and granular, and dull red or pink, and it may have a seropurulent secretion. *Treatment* is cauterization with silver nitrate, repeated at intervals of several days until the base is dry.

Umbilical granuloma must be differentiated from **umbilical polyp,** a rare anomaly resulting from persistence of all or part of the omphalomesenteric duct or the urachus. The tissue of the polyp is firm and resistant, is bright red, and has a mucoid secretion. If the polyp is communicating with the ileum or bladder, small amounts of fecal material or urine may be discharged intermittently. Histologically, the polyp consists of intestinal or urinary tract mucosa. Treatment is surgical excision of the *entire* omphalomesenteric or urachal remnant.

Infections.

Although aseptic delivery and routine cord care (daily application of triple dye to the umbilical stump and surrounding skin) decrease the risk of umbilical infection, the necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. Omphalitis may remain localized or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, or the liver. Infants with abdominal wall cellulitis or those with necrotizing fasciitis have a high incidence of associated bacteremia. Portal vein phlebitis may develop and result in the later onset of extrahepatic portal hypertension. The general manifestations may be minimal (periumbilical erythema), even when septicemia or hepatitis has resulted. *Treatment* includes prompt antibiotic therapy (effective against *Staphylococcus aureus* and *Escherichia coli)* and, if abscess formation has occurred, surgical incision and drainage.

Umbilical Hernia.

Often associated with diastasis recti, an umbilical hernia is due to imperfect closure or weakness of the umbilical ring. Predisposing factors include black race and low birthweight. The hernia appears as a soft swelling covered by skin that protrudes during crying, coughing, or straining and can be reduced easily through the fibrous ring at the umbilicus. The hernia consists of omentum or portions of the small intestine. The size of the defect varies from less than 1?cm in diameter to as much as 5?cm, but large ones are rare.

TREATMENT.

Most umbilical hernias that appear before the age of 6 mo disappear spontaneously by 1 yr of age. Even large hernias (5–6?cm in all dimensions) have been known to disappear spontaneously by 5–6 yr of age. Strangulation is extremely rare. It is generally agreed that “strapping” is ineffective. Surgery is not advised unless the hernia persists to the age of 4–5 yr, causes symptoms, becomes strangulated, or becomes progressively larger after the age of 1–2 yr. Defects exceeding 2?cm are less likely to close spontaneously.

Chapter 95 - Metabolic Disturbances

Barbara J. Stoll
Robert M. Kliegman

HYPERTHERMIA IN THE NEWBORN (TRANSITORY FEVER OF THE NEWBORN, DEHYDRATION FEVER)

Elevations in temperature (38–39°C or 100–103°F) are occasionally noted on the 2nd–3rd day of life in infants whose clinical course has been otherwise satisfactory. This disturbance is especially likely to occur in breast-fed infants whose intake of fluid has been particularly low or in infants exposed to high environmental temperatures, either in an incubator, in a bassinet near a radiator, or in the sun.

The infant may lose weight. However, a consistent relationship may not be seen between the fever and the extent of weight loss or inadequacy of fluid intake. Urinary output and the frequency of voiding diminish. The fontanel may be depressed. The infant takes fluids avidly, but the apparent vigor of the infant contrasts with the usual appearance of “being sick” in the presence of infection. The rise in temperature may be associated with an increase in serum levels of protein and sodium and with an increase in hematocrit. The possibility of local or systemic infection should be evaluated. Administering oral or parenteral fluids or lowering the environmental temperature leads to prompt reduction of the fever and alleviation of symptoms.

A *more severe form of neonatal hyperthermia* occurs in both newborn and older infants when they are warmly dressed for outdoor low temperatures that do not exist in their immediate indoor environment. The diminished sweating capacity of newborn infants is a contributing factor. Warmly dressed infants left near stoves or radiators, traveling in well-heated automobiles, or left with bright sunlight shining directly on them through the windows of a closed room or automobile are likely to be victims. Excess clothing in hot weather, especially when the infant is left in the sun, is a less common cause. Body temperature is often as high as 41–44°C (106–111°F). The skin is hot and dry, and initially the infant usually appears flushed and apathetic. Tachypnea and irritability may be noted. This stage may be followed by stupor, grayish pallor, coma, and convulsions. Hypernatremia may contribute to the convulsions. Mortality and morbidity rates (brain damage) are high. Hyperthermia has been associated with sudden infant death and with *hemorrhagic shock and encephalopathy syndrome* (Chapter 57.2). The condition is prevented by dressing infants in clothing suitable for the temperature of the *immediate* environment. In newborn infants, exposure of the body to usual room temperature or immersion in tepid water usually suffices to bring the temperature back to normal levels. Older infants may require cooling for a longer time by repeated immersion or by the use of a water-cooled mattress or other apparatus for induction of hypothermia. Attention to possible fluid and electrolyte disturbance is essential.

NEONATAL COLD INJURY

Neonatal cold injury usually occurs in abandoned infants or those in inadequately heated homes during damp cold spells when the outside temperature is in the freezing range (see Chapter 63).

The initial features are apathy, refusal of food, oliguria, and coldness to touch. The body temperature is usually between 29.5 and 35°C (85–95°F), and immobility, edema, and redness of the extremities, especially the hands, feet, and face, are observed. Bradycardia and apnea may also occur. The facial erythema frequently gives a false impression of health and delays recognition that the infant is ill. Local hardening over areas of edema may lead to confusion with scleredema. Rhinitis is common, as are hypoglycemia and acidosis. Hemorrhagic manifestations are frequent; massive pulmonary hemorrhage is a common finding at autopsy. Treatment consists of warming and paying scrupulous attention to recognizing and correcting hypotension and metabolic imbalances, particularly hypoglycemia. Prevention consists of providing adequate environmental heat. The mortality rate is about 10%; about 10% of survivors have evidence of brain damage.
